Link Plus Methods

Link Plus implements a probabilistic record linkage algorithm developed by Fellegi and Sunter [1], called the Fellegi-Sunter methodology; the formal mathematical models involved in this methodology underpin most modern record linkages (see Herzog and Scheuren [2] for review). A recent study [3] comparing linkage methods commonly used in public health reports that programs based on the Fellegi-Sunter method (including, but not limited to, Link Plus) maximize the number of true matches identified, given their high degree of sensitivity (i.e., the proportion of true matches identified by the algorithm) and precision (i.e., the proportion of matches identified by the algorithm that were true matches). By contrast, programs based on deterministic matching algorithms exhibit high precision but low sensitivity, and thus perform poorly when using lower quality data (i.e., misspelled or missing fields). Such programs may induce systematic bias due to the exclusion of record-linkages for lower SES and racial-ethnic minority populations [4].

In general, Link Plus proceeds through the following steps. First, the program identifies potential matches by 'blocking' record pairs with exact values on a user-specified field. These comparison-pairs then receive a match score based on similarity of specified 'match' variables; pairs with higher scores appear more likely to reflect 'true' matches. Next, the user sets a lower-bound match score, above which he / she / they can review pairs and assign designations of 'true match,' 'uncertain,' or 'no match.' Pairs with match scores below the specified lower-bound receive a 'no match' designation and are dropped.

I used Link Plus to 'block' records based on birthing persons' date of birth. Potential matches (i.e., all record pairs with the same date of birth) then received match scores according to similarity of a birthing person's first and last name, as well as the other parent's date of birth. Match scores ranged from 0 (pairs with the same birthing person's date of birth but differing on all other variables) to approximately 25 (pairs matching on all variables). In order to consider a broad range of matches and avoid dropping potential low-scoring 'true matches,' I set a lower-bound match score of 5.0, above which comparison-pairs received a temporary designation of 'uncertain.'

I created user-defined categories to sort these remaining 'uncertain' comparison-pairs. I assigned pairs matching on all variables to one category, pairs matching on birthing person's last name and other parent's date of birth (but not birthing person's first name) to a second category, and those matching on birthing person's first and last name (but not other parent's date of birth) to a third category. I excluded from review comparison-pairs not included in these

three categories. I designated pairs in the first category (matching on all variables) as 'true matches.' For pairs in the second and third category, I assigned a 'true match' designation only to those in which the date of birth for record 1 (first sibling) corresponded with the date of last delivery for record 2 (second sibling). This process yielded 1,340,676 'true match' pairs, representing birthing persons with at least two consecutive live singleton births in California between 2005 and 2015.
