Abstract: *Research Highlights:* Our study establishes the biennial nature of flowering intensity as a life-time energy-conserving strategy; we show unexpectedly high flower:fruit ratios despite extensive predation of buds and flowers by insect larvae; ‘selective’ bud abortion may be a key annual energy-saving strategy. *Background and Objectives:* We aim to explain the strongly biennial flowering pattern of *Eschweilera tenuifolia*, an ecologically key tree species of Amazon blackwater-flooded forest, inundated for up to nine months annually, and with large flowers (6 cm in width). *Materials and Methods:* We quantified the insect infestation of central Amazonian *Eschweilera tenuifolia* buds and flowers; we measured nectar production from flower opening onwards, examined flower duration and monitored pollen theft. We tested the role of infestation in bud abortion, nectar production and fruit production initiation. *Results:* Our study shows extensive predation of buds and flowers by insect larvae, as well as selective abortion of heavily infested buds, and limited loss to pollen thieves which fed largely on infertile fodder pollen. Nectar production peaked in the morning, with no nocturnal nectar production recorded. Sucrose levels were similar to congeneric values (mean 37.4%), and near-constant during production. Flower duration (4–5 days) was longer than reported for other congenics. *Conclusions:* Insect infestation of buds can play an important role in regulating flower:fruit ratios, thus setting limits on individual total seed set. Individual *Eschweilera tenuifolia* appear to invest highly in reproduction every second year. Extended flower duration may be a strategy to enhance pollination success, but increases overall reproductive investment. Abortion of heavily infested buds may minimize allocation of energy to malformed flowers, which have a lower chance of attracting pollinators, thus functioning as a short-term energy-saving strategy. Additionally, biennial flowering in *E. tenuifolia* is likely to be an energy-conserving response in a

highly physiologically-challenging environment. Thus, *E. tenuifolia* exhibits energy-conservation strategies at two divergent temporal scales.

Keywords: nectar production; bud abortion; insects; invertebrate bud predation; flower:fruit ratio; *igapó*; reproductive strategy

1. Introduction

The Lecythidaceae is a tropical plant family of 300 species in 20 genera and three subfamilies [1], of which one, Lecythidoideae, is exclusively neotropical. One genus in the Lecythidoideae, *Eschweilera*, is a speciose clade of trees (94 species: Mori and Prance [2,3]; Tropicos [4]—though see Mori et al. [1]). Although the genus occurs from southern Mexico (*E. mexicana* T. Wendt, S.A. Mori and Prance) to southern Brazil (*E. compressa* [Vell.] Miers) and Trinidad (3 spp., incl. *E. decolorans* Sandwith), *Eschweilera* has its greatest diversity in the Amazon basin [2]. The lowland Amazon may have 6–17 sympatric congeneric species in unflooded lowland forest (*terra firme*) [5–7], and members of the genus may dominate both numerically and by Importance Value Index [6–10]. Indeed, *Eschweilera coriacea* is considered by ter Steege et al. [11] to be one of the Amazon’s hyper-dominant tree species. While the majority of *Eschweilera* species occupy *terra firme* and other non-flooded habitats, a few species (e.g., *E. ovifolia* (DC.) Nied., *E. parviflora* (Aubl.) Miers, *E. pedicellata* (Rich.) S.A. Mori, and *E. tenuifolia* [O. Berg] Miers) occupy the seasonally-flooded forests of the Amazon basin.

Here we report on the flowering phenology, patterns of nectar production and animal interactions for *E. tenuifolia*, a species which inhabits seasonally-flooded forest present on the margins of low-sediment, clear, and blackwater rivers (*igapó*—*sensu* Prance 1979: as clear and blackwater forms of *igapó* are floristically distinct, we will use the word ‘*igapó*’ in this paper to refer purely to the seasonally-flooded forests on the margins of blackwater rivers) (Figure 1A).

Figure 1. (A) An isolated individual of *Eschweilera tenuifolia* in the low water season. Flood water will touch the underside of the canopy when river-levels are highest. (B) Inflorescence of *E. tenuifolia*, showing buds at varying stages of development, and open flower with clearly visible androecium. Photos: Daniel Praia.

Eschweilera tenuifolia occurs in the *igapós* of central Amazonia, where it is a dominant member of the plant assemblage and an important species in the general ecology of the region. It is a key

component in the diet of primates, parrots, macaws, and moths, and forms part of the diet of arboreal rodents [12,13] (Table 1). Trunks of large trees are hollow and provide roosts for bats and other mammals (Table 1). Following seed shed, those parts of dehisced fruits that remain on trees are used as refuges by invertebrates for nests (wasps and ants) and webs (spiders; Table 1). Seven *igapó*-inhabiting species of the genus *Eschweilera* are known to harbor galls on the leaves and bud tips [14]. Although *E. tenuifolia* is the most abundant member of this genus in *igapó* [15], insect galls have not been documented in this species, which may, potentially, be due to the high level of bioactive chemicals in *E. tenuifolia* [16]. However, despite the presence of chemical substances, the species interacts with other *igapó* plants alone or in association with animals (Tables 1 and 2).

Table 1. Interactions between *Eschweilera tenuifolia* (Lecythidaceae) and *igapó* animals.

Taxon	Plant Part	Interaction	Reference
<i>Mammals</i>			
Golden-backed uacari (<i>Cacajao ouakary</i> Spix 1823)	Open flowers	Destructive feeding on flowers	[12]
	Immature seeds	Extracting and eating seeds from pyxidium. Some dispersal. Seeds over 50% of diet in some months	[12,17,18]
	Germinating seeds	Predation of germinating seeds on the floor of <i>igapó</i> forest, when <i>igapó</i> unflooded.	[17,19,20]
	Young leaves	Ingestion of young leaves shortly after leaf flush	[12]
White-fronted capuchin (<i>Cebus albifrons</i> [Humboldt 1812])	Open flowers	Destructive feeding on flowers	[12]
	Hollow trunk	Predation of <i>Artibeus</i> sp. bat roosting inside hollow	AA Barnett (unpublished data)
Northern Amazon squirrel (<i>Urosciureus igniventris</i> [Wagner 1842])	Immature seeds	Extricating and eating from pyxidium	[13]
Five of rodent and two marsupial species,	Germinating seeds	Eaten when on floor of unflooded <i>igapó</i> , at multi-species seed patches	[20]
Collared peccary (<i>Pecari tajacu</i> [Linnaeus 1758])	Germinating seeds	Eaten when on floor of unflooded <i>igapó</i> , at multi-species seed patches	[20]
Brown brocket deer (<i>Mazama nemorivaga</i> [F. Cuvier 1817])	Leaves of germinating seeds	Browsed from stems of germinating seeds when part of multi-species seed patches	[20]
Lesser fishing bat (<i>Noctilio albiventris</i> Desmarest 1818)	Hollow trunk ¹	Colony roosting within hollow trunk during non-flooded season.	[21]
Stripe-backed Sac-winged bat (<i>Saccopteryx bilineata</i> [Temminck 1838])	Bark	Roosts on outside of trunk	[21]
White-winged Dog-faced bat (<i>Peropteryx leucoptera</i> Peters 1867)	Bark	Roosts on outside of trunk	[22]
<i>Birds</i>			
Macaws: Blue-and-yellow (<i>Ara ararauna</i> [Linnaeus 1758]), Red-and-green (<i>A. chloropterus</i> [Grey 1859]), Scarlet (<i>A. macao</i> [Linnaeus 1758])	Immature seeds	Predation of immature seeds while on trees	[12,13]
Amazon Parrots: Orange-winged (<i>Amazona amazonica</i> Lesson 1830), Red-lored (<i>A. autumnalis</i> [Linnaeus 1758]), Mealy (<i>A. farinose</i> [Boddaert 1783])	Immature seeds	Predation of immature seeds while on trees	[12,13]
<i>Fish</i> ²			
Tambaqui (<i>Colossoma macropomum</i> [G. Cuvier, 1818]),	Mature seeds	Ingested when, following pyxidial dehiscence, seeds are floating on the surface of <i>igapó</i> waters as part of hydrochorous dispersal.	[23–25]; AA Barnett (unpublished data)
Pacu (<i>Mylossoma</i> sp.)	Mature seeds	Ingested	[23–25]
Pirapitinga (<i>Piaractus brachipomus</i> [G. Cuvier, 1818])	Mature seeds	Ingested	[23–25]

Table 1. Cont.

Taxon	Plant Part	Interaction	Reference
<i>Invertebrates</i>			
Freshwater sponges (Demospongiae)	Trunks below flood line	A generalist interaction as sponges also use many other trunks as a growth substrate.	[26,27]
Hunting spiders (<i>Ancylometes</i> sp. Pisauridae: possibly <i>A. jau</i> [28]).	Trunks just above the current waterline	A generalist interaction, as these arachnids also use many other trunks as resting and hunting substrates.	[28]
Ant (<i>Dolichoderus bispinosus</i> [Olivier, 1792])	Developing pyxidia	Seen feeding on unidentified material on pyxidia surfaces (possibly exudate from insect boreholes). The species is aggressive, widespread and exclusively arboreal.	[29]
Clearwing moths (<i>Carmenta</i> sp[p], Sessidae)—caterpillars	Immature seeds ³	Fed on reserves of developing seeds (contiguous feeding trails show individual caterpillars may feed on multiple seeds within pyxidium)	[12,30,31] ⁴
Moths (four morpho-species)—caterpillars	Developing pyxidia	Found within the developing pyxidia	AA Barnett & RHP da Silva (unpublished data)
Seed weevil (Buchinae)	Developing pyxidia	Found within the developing pyxidia	AA Barnett & RHP da Silva (unpublished data)
Centipedes, woodlice, scorpions, pseudoscorpions, ants and beetles	Pyxidia with damaged and/or rotting seeds and partly broken excarp	Live in pyxidia	AA Barnett & RHP da Silva (unpublished data)
Wasps (<i>Mischocyttarus</i> spp.), and webs of three spider morphotypes	Non-abscised bases of dehisced pyxidia	Inverted and shaped like umbrellas, these act as shelters for a wide variety of invertebrates ⁵ , including nests (<i>Mischocyttarus</i> wasps) and webs (spiders)	AA Barnett (unpublished data)
Skipper butterflies (Hesperiidae, Lepidoptera)—caterpillars	Young leaves	Feeding	[30]
Stingless Bees (<i>Melipona</i> and <i>Scaptotrigona</i> spp.)	Pollen and nectar	Known to remove pollen from <i>E. tenuifolia</i> flowers, but may not be effective pollinators	[32]

¹ The hollow nature of their trunks means that *terra firme* members of the genus are used in this way by bats [22,33].

² In other flooded forest species, such as *E. ovalifolia*, seeds are surrounded by a thin white fleshy sarcotesta, and the seeds are ingested, then dispersed, by fish [34]. However, *E. tenuifolia* lacks any such arilate tissue and the seed coat is corky and acts only as a floatation device [35]. Seeds of *E. tenuifolia* are also considerably larger than those of *E. ovalifolia* (2.8–5 cm length vs. 3–3.5 cm diameter: [35]). This, plus their respective shapes (fusiform vs. pulviniform), means that observed fish-seed interactions for *E. tenuifolia* (e.g., with *Colossoma macropomum*, a typical igapó seed predator fish: [25]), were likely to be purely predatory. ³ While larvae of most members of this family are wood-borers, several exploit hard seeds [36]. Species of the genus *Carmenta* have been raised from seeds from a variety of Neotropical plant families, including Lecythidaceae (*Eschweilera* and *Gustavia*: [37]).

⁴ Though larval sessids, attributed to the genus *Carmenta* were recorded by both Maia [31] and Barnett [12] from *E. tenuifolia* seeds, the illustrated adults have different appearances. As the study sites were on opposite sides of the Rio Negro, they may represent different taxa. ⁵ Similar interactions occur with the pyxidea of *terra firme* species, except that, instead of providing rain-shelters they often provide pools of water on the otherwise pool-less forest floor (e.g., *Bertholletia excelsa* [38]; *Gustavia superba* [39]).

The igapó forest inhabited by *E. tenuifolia* is inundated for up to 10 months of the year by floodwaters up to 7 m (Figure 1A). Consequently, igapó forest tree species show a variety of physiological and anatomical adaptations to this extended flooding and accompanying anoxia [40].

Table 2. Interactions between *Eschweilera tenuifolia* (Lecythidaceae) and other igapó plants, and subsequent interactions with igapó animals.

Type of Plant	Interactions	Reference
Epiphytes		
Wide-ranging, sun-tolerant species such as <i>Philodendrum solimoensis</i> A.C. Sm (Arecaceae) and <i>Aechmea mertensii</i> (G. Mey.) Schult. & Schult.f (Bromeliaceae).	<i>Pionus</i> parrots and <i>Saimiri</i> monkeys seen eating infuscences of <i>P. solimoensis</i> on <i>E. tenuifolia</i> . An unidentified hummingbird was seen visiting <i>A. mertensii</i> inflorescences on several occasions. <i>Cacajao ouakary</i> ate the leaf bases of <i>A. mertensii</i> —though it was unclear if this was for the succulent water-rich material there, or the larvae of <i>Metamasius</i> weevils known to inhabit these areas ⁷ .	Barnett et al. (unpublished data) ⁷ [41]
Occasionally, <i>Selenicereus wittii</i> (Cactaceae) was seen, addressed to the main trunk, but only above the highest water-mark. The water-dispersed orchid <i>Galeandra devoniana</i> M.R. Schomb. ex Lindl was also quite common on smaller specimens whose canopies were inundated annually. More shaded specimens had colonies of <i>Codonanthopsis crassifolia</i> (H. Focke) Chautems & M. Perret (Gesneriaceae), a creeping herb ⁸ .	<i>Selenicereus wittii</i> is reported to be pollinated by <i>Amphimoena</i> and <i>Cocytius</i> hawkmoths ⁹ , but no flowering individuals were found for confirmatory observation. Euglossine bees were seen visiting the flowers of <i>G. devoniana</i> , these are the putative pollinator of the species ¹⁰ . Colonies of <i>C. crassifolia</i> are obligately associated with colonies of <i>Crematogaster longispina</i> (Formicidae) ¹¹ , in whose nests they are rooted. Leaves were eaten by <i>C. ouakary</i> (who would rip of a part of the plant and eat it at a distance to avoid the ants) ¹² . Members of the genus are pollinated by small bees ¹³ —this was confirmed by field observation, though taxa could not be captured for identification.	⁸ [42,43] ⁹ [44] ¹⁰ [45] ¹¹ [46] ¹² [12] ¹³ [47]
<i>Phoradendron poeppigii</i> Van Tiegh.) Kuijt (Santalaceae)	Individuals of this mistletoe species were seen occasionally on <i>E. tenuifolia</i> trees. Immature inflorescences were removed and eaten by <i>C. ouakary</i> . Euphonias and other small birds removed fruits.	[12]
Root parasites <i>Helosis cayannensis</i> (Sw.) Spreng. (Balenophoraceae)	When igapó was unflooded inflorescences and above-ground stypes of these obligate, but non-host specific, root parasites were seen close to <i>E. tenuifolia</i> trunks and exposed roots ¹⁴ . Inflorescences were seen being visited by small flies (Tachnidae). These are considered the main pollinator in this genus ¹⁵ , though weevils of the subtribe Oxycorynina (Belidae: Oxycoryninae), which are only found in association with Baleophoraceae, may also be involved ¹⁶ .	¹⁴ [48] ¹⁵ [49] ¹⁶ [50]

Varying levels of inundation tolerance lead to marked banding-like zonation in the species composition of the igapó tree assemblage [51]. Of these, *E. tenuifolia* is one of the most highly adapted to prolonged inundation [52]. Such tolerance means it can be found throughout the igapó forest [51], and it may form near-monodominant stands (*macacari-curizais*) in areas where inundation is too prolonged for other species to survive [53]. The rigors of life in such a challenging environment mean that individuals grow very slowly (1.5–1.7 mm per year), although for extended periods (400–800 years [54]). Phenology is strongly linked to the seasonal inundation pulse in igapó [55], starting as the water level drops, continuing through the brief period when the igapó forest floor dries up, and until the start of the new flooding season [31,56]. Individuals may reach 18 m in height, and have canopies with surface areas of up to 29 m², and up to 106 inflorescences per canopy simultaneously [12]. Mass of seeds produced per year is substantial, with means of 55 g per m² of canopy, and 5798 g per plant [12]. However, while collectively the fruit and flowers of the species are available every year, it is rare for individual plants to flower abundantly in two sequential years (AA Barnett and W Souza Silva, unpublished data). Thus, the general pattern is a high-yield year followed by a low-yield year. While this is not biennially in the strictest sense, it is such a strongly marked alternate year pattern, that we believe it can functionally be treated as such.

In the genus *Eschweilera*, flowers are strongly zygomorphic and heterantheric. Flowers are large, robust and fleshy, with the infertile stamens on one side of the androecium fused and form a hood covering the ovary (Figure 1B), within which lies the source of nectar. Below lies a staminodal ring which contains anthers with fertile pollen [57,58]. The floral biology of *E. tenuifolia* has only been studied previously in terms of phenology [56]. However, studies of other members of the genus (*E. bogotensis* R.Knuth. [59]; *E. decolorens* [58]; *E. garagarae* Pittier [60]; *E. longipes* Miers [58]; *E. nana* [O.Berg] Miers [61]) have reported the presence of nectar at the end of the coiled section of the non-differentiated tissue in the androecial hood. This nectar is accessible once a pollinating bee forces open the hood. Such bees usually land on top of the androecial hood, then invert their bodies and, in this sternotribic position, push themselves into the gap between the basal ring and androecial hood. They then move in further to reach the nectar, receiving pollen from the fertile anthers of the basal ring in the process [62]. Together, the size and weight of the hood greatly reduce ingress by smaller-bodied nectar and pollen thieves [63]. Members of the Xylocopine genus *Xylocopa* and the Euglossine genus *Eulaema* are known pollinators for *Eschweilera* (e.g., *E. decolorans* and *E. longipes* [58]; *E. ovata* [64]; *E. nana* [65]). Members of the Meliponin stingless bee genera *Melipona* and *Scaptotrigona* remove pollen from *E. tenuifolia* [32]. However, many meliponines are pollen thieves [66,67], including of Lecythidaceae [68], so it is not yet certain whether they are true and effective pollinators. The flowers are the focus of a complex interaction between xylocopid bees and golden-backed uacari monkeys (*Cacajao ouakary*), where the presence of the former appears to deter the latter from eating *E. tenuifolia* flowers (AA Barnett, unpublished data). Although some members of the closely-related [69] genus *Lecythis* are night-pollinated (e.g., *Lecythis poiteaui* O. Berg, principally pollinated by bats, but also visited by bees and moths [57,70]), all known members of the genus *Eschweilera* are day-pollinated [2,65].

Fruit in all Lecythidaceae are in the form of a lidded pyxidium, which may or may not be dehiscent [71] (Figure 2) Such fruits are often large and with a highly sclerified pericarp. In addition, levels of seed set in the genus appear to be very low (1.48% for *E. bogotensis* [59]; 0.0036% for *E. nana* [65]), and this is also true for many members of the family. It has been suggested that the low level of seed set is due to soil nutrient poverty [72] and energetic limitation caused by investment in such energetically-demanding fruit [59].

Figure 2. Mature pyxidium of *Eschweilera tenuifolia*, showing multiple seeds and dehiscent cap. Photo: Naara Ferreira da Silva.

However, despite the numerical and ecological importance of the species in *igapó*, phenology of *E. tenuifolia* has been the subject of only one focal study, conducted by Maia [31] (see also Maia and Peidade [56]). This 17 month study showed that *E. tenuifolia* follows a leaf drop/leaf flush/flowering pattern (one of the three phenological patterns identified for Lecythidaceae by Mori and Prance [3]), and had the flowering form termed “steady-state flowering” by Gentry [73]. Maia [31] also found both leaf and flower production to be strongly linked to the annual flood pulse, with an annual leaf flush in August, and flower production extending across five months (September through January) during the ebb, lowest water, and flooding periods in *igapó*. The species was classified as deciduous (“bare of leaves for at least three weeks”) by Parolin et al. [74]. The only other phenological study of an *igapó* member of the genus, *E. parviflora*, reported a similar temporal patterning: the timing was offset depending on the extent of inundation [75]. However, both studies [31,75] left open several key questions regarding the floral biology of *Eschweilera*.

Accordingly, we undertook a study of the floral ontogeny, the extent of insect predation of developing flower buds, and the diel cycle of nectar production in *E. tenuifolia*, quantifying flower size and weight and speed of development, to test the following predictions:

- (1) Insect predation of *E. tenuifolia* flower buds and flowers will be high (operationally defined as over 50 % of buds).
- (2) High levels of bud and flower insect infestation will result in low flower:fruit ratios.
- (3) Visitation of anthers by pollen predators will occur only once flowers have opened and access is thus facilitated.
- (4) Nectar production will occur during daylight hours, and nectar characteristics will meet the criteria for bee-pollinated plants.

2. Materials and Methods

2.1. Study Habitat: Igapó

In *igapó*, inundations may reach 7 m and last for up to 10 months (Prance [76]). *Igapó* is characterized by a comparatively low per-hectare tree species richness (approximately 60/ha [52], compared to 120–200/ha in neighboring never-flooded forests [77], and a flowering and fruiting phenology that is linked to the annual peaks in river water levels [78]. Because of the low-sediment content of their waters, the floodplains of blackwater rivers are not extensive, rarely exceeding 200 m in width [79]. However, differences in inclination are sufficient to generate differences in inundation duration across this distance that last from 1 to 10 months. Differences in flood tolerance mean tree species have banded horizontal distributions within the *igapó*, as well as vertically on hummocks (*borokotoh*) within it [51].

2.2. Study Site

Jaú National Park (1°53'15" S, 61°41'25" W) is a 2.2 million ha protected area that forms part of the 6 million ha Central Amazonian Ecological Complex [80]. It is located on the south bank of the Rio Negro, some 230 km upstream from Manaus, the capital city of Amazonas State, Brazil (Figure 3). Regional climate is typical of that for the central Amazon Basin, with seasons defined by rainfall and river flooding. Flooding is highest during June and July, when floodwaters can reach 6–10 m. Average rainfall varies between months, being 1750 mm between July and September and 2500 mm from December to April. In May–June and October–November, there is usually little rain [12]. The predominant habitat in Jaú National Park (JNP) is never-flooded, lowland tropical forest (*terra firme*: approximately 80% of the park), followed by seasonally-inundated river-margin forest (*igapó*: 12% of the park), white sand vegetation (*campina*: 4%), and palm and aroid swamps (*buritizal* and *aningal*, respectively: 3% of the park [51]). The human population does not exceed 1000 people and human-modified areas cover less than 0.1% of the park surface. Additional information on the vegetation at JNP can be found in Ferreira and Prance [77] and Vicentini [81].

Figure 3. Map, showing location of Jaú National Park (JNP), within Brazilian Amazonia showing study locations within Jaú National Park, central Brazilian Amazonia, based around the villages at Patuá and Seringalzinho. For descriptions of sites i–iii, see Table 3. Cartography: Natalia Kinap.

Table 3. Type of sampling effort and its spatial and temporal distribution.

Study Area (See Map, Figure 4)	Study Type	Prediction Associated with	Year(s)	Number of Individual Trees Sampled
i (Seringalzinho)	Preliminary data on flower ontogeny and timing of nectar yields	4	1999	12 (outside the 2006–2008 phenology plots)
ii (Patuá)	Number of inflorescences per canopy	X (supplementary data)	2006–2008	Counted for all 134 <i>E. tenuifolia</i> trees (of 137 present and above 10 cm DBH) ¹ that flowered in 2007
ii (Patuá)	Survivorship of flower buds to button stage of fruit production	2	2006–2008	Marked buds from the 130 trees in the phenological study plots that produced fruit
ii, iii (Patuá)	Collection of aborted buds and flowers	2	2006–2008	No specific trees involved; material collected <i>ad libitum</i> when encountered floating on water surface.
iii (Patuá)	Analysis of the extent of invertebrate infestation of flowers and flower buds	1, 3	2006–2008	396 buds and 200 flowers from 11 trees outside the phenology study plots

¹: DBH = Diameter at Breast Height.

Figure 4. *Eschweilera tenuifolia* fruits—Mature pyxidia (above), and immature “button stage” pyxidia (below). Photo: Adrian Barnett.

Within JNP National Park, initial studies were conducted during visits to the Seringalzinho region (1999) and Patuá (2000) regions (see [13,21,82–84]). The main study took place between October 2006 and April 2008, as part of a broader study of golden-backed uacari (*C. ouakary*) ecology [30,85,86]. Follow-up data were collected during a return visit to Seringalzinho in 2015 (for all study locations, see Figure 3.)

2.3. Field Measures

Data were collected from three areas within the park: (i) a *macacaruizal* near the village of Seringalzinho; (ii) the area near the village of Patuá bounded by six 0.25 ha plots used to monitor *igapó* phenology during the 2006–2008 study; (iii) the remainder of the 2000 ha area used to study the ecology of the golden-backed uacari in 2006–2008 [12,51,87] (Figure 3; Table 3). In total, data were gathered from 194 individual *E. tenuifolia* trees (originally $N = 197$, but three trees were excluded when they did not flower). For clarity, the distribution of sampling effort is shown in Table 3, with the locations of each study shown in Figure 3).

To test predictions 1–4, we implemented the following field techniques, for which data were collected from paddled wooden canoes during ecological field studies of uacari monkeys (see [88] for details on overall field methods).

Prediction 1—Insect predation of *E. tenuifolia* flower buds and flowers will be high. A total of 200 open *E. tenuifolia* flowers and 396 buds were removed from a total of 11 *E. tenuifolia* trees that were not used in any other part of the study. Buds and flowers were numbered, stored in lidded containers, and then processed within two hours at the field station lab. Buds and flowers were then measured, graded for size, and weighed in units of 10 similar-sized units using an electronic balance (Salter-1250). All were examined for indications of the presence of invertebrates (larvae of Coleoptera, Diptera, Lepidoptera; imago of thrips (Order Thysanoptera), aphids and small beetles such as staphylinids, plus mites), or their signs (burrows, emergence holes, frass, discoloration). Thrips were identified using characters in Mound [89]. To calculate mean weights of contained material, plant material was reweighed after invertebrates were removed (reliable measures of resident insect mass at the individual bud or flowers level was not adopted, due to the 0.1 g sensitivity of the balance).

To analyze insect content, flowers were individually dissected with a scalpel, and encountered insects removed. All collected specimens were identified to class, then stored in 70% ethanol. For comparative analysis, buds were divided into four operational size-based classes: stage 1 (S1): small buds, maximum diameter 4 mm; stage 2: medium 4–8 mm; stage 3: medium–large buds, 8–10 mm; and stage 4: large buds 12 mm and above, with petals just beginning to unfurl. The sequence was completed by opened flowers (stage 5).

When retrieving infesting insects, the extent of damage made by burrows and feeding activity was estimated by eye into five categories: no (obvious) damage; light (obvious damage to 25% of androecium); medium (obvious damage to 25 to 50% of androecium); medium–heavy (obvious damage to 50 to 75% of androecium); and heavy (obvious damage to more than 75% of androecium).

Prediction 2—The high levels of bud and flower insect infestation will result in low flower: fruit ratios. To track fruit development to the button stage of pyxidial growth (Figure 4), individual inflorescences on trees in the phenology study plots were marked on the peduncle with a number written in waterproof ink (initial attempts to use flagging tape or fine cords for marking, as used in several *Bertholletia* studies and by Krause [64] for *E. ovata*, were not successful due to squirrels removing the items for use as nesting material). This pyxidial development stage was chosen since it is not one consumed by the major fruit predators of *E. tenuifolia*, macaws (*Ara* spp.), and the primate *C. ouakary* [12,13]. Since it was possible that, once a flower was pollinated, others in an inflorescence would be aborted or, resources selectively diverted at some point in the maturation process to one fruit on an inflorescence, a single flower was marked on 5 inflorescences on each of the 134 trees that produced flowers in 137 of the phenology study plots, for a total of 670 flowers. Progress was tracked during monthly phenology recording visits. In addition, all encountered fallen buds and flowers were collected when encountered. If both the stem and basal plate of the pedicel of a fallen bud was intact, that bud or flower was considered to have been aborted and was then analyzed by the extent of internal damage, as categorized above.

Prediction 3—Visitation of anthers by thrips and other invertebrate pollen predators will occur only once flowers had opened and access was facilitated. Small invertebrates (thrips, mites, and other taxa) were extracted from the surface of the infertile anthers with a small paintbrush, counted, and stored in alcohol-glycerin-acetic acid, following Lewis [90]. This extraction was performed for both flower buds and open flowers.

Prediction 4—Nectar production will occur during daylight hours, and will be constant across the production period. In 1999, a sample of 360 undamaged flowers was used, with 10 sampled at hourly intervals from 06.00 to 18.00 h. We used three sets of 120 flowers per day, with a different set of 120 flowers from a different set of 12 trees on each of three successive days, to avoid any possible responses by trees to flower removal during sampling). To avoid any effects that flower damage during sampling might have on nectar production, each flower was sampled just once: it was removed from the tree and nectar accessed following a longitudinal cut across along the androecium hood [64]. Nectar sugar concentration was measured with a Brix refractometer [91], and volume production estimated with a graduated 5 μ L micropipette and calipers [92,93]. In addition, nocturnal nectar production in *E. tenuifolia* flowers was assayed with sampling at 22.00 and 00.00 h in 1999, and at 02.00 and 04.00 h in 2000. In 1999, 16 flowers from three trees (3, 6, and 7 flowers each) were sampled at 22.00 h, and 11 from a single tree at 00.00 h. In 2000, 9 and 17 flowers were sampled from two individual trees, at 02.00 and 04.00 h, respectively. These trees were selected from those used for sampling diurnal nectar volumes.

2.4. Statistical Analysis

Regression analysis was used to test for a relationship between the number of inflorescences per crown and crown size, and between the number of inflorescences per crown and diameter at breast height (DBH).

A chi-square test was used to test for a difference between the proportion of buds and of open flowers that were infested by invertebrates. This was performed both for each bud development category, and for all bud categories combined. A Kruskal–Wallis test was used to test for differences in insect mass between buds and the open flowers. In both infestation rates and insect mass, comparisons were made between flowers and each bud development category (stages 1–4) separately, and then for all bud categories combined. A Mann–Whitney U test was then used to test for differences between buds and flowers in the percentile of the plant material (bud or flower) that these total insect masses

represented. Because of the possibility that insect larvae would enclose before the flower opened, a Mann–Whitney U was used to test whether there were differences in infestation rates between stage 3 buds and flowers and, separately, between stage 4 buds and flowers. A chi-square test was used to test for differences in infestation rates across the four bud development stages, stage 1 to stage 4.

Mann–Whitney U tests were used to test for a difference in infestation rates between open flowers and buds (with the smallest bud class excluded); a difference in insect mass between buds and open flowers (all development stages combined); and a difference in insect mass between buds (in stages 3 and 4) and open flowers. Chi-squared tests were used to test for differences in the percentage of pollen predators in buds versus flowers; a difference in damage rates between aborted and non-aborted buds (all developmental stages combined); a difference in damage rates between aborted and non-aborted buds within each of the four size classes of buds; and a difference in damage rates between aborted and non-aborted flowers.

Lastly, the regularity of nectar production was analyzed with a Mann–Whitney U test by comparing both the nectar volumes and concentrations produced for hourly diel samples. We then ran a regression to test whether nectar volume and nectar concentration (separate regressions) increased linearly from early morning to afternoon. All statistical analyses were conducted using SPSS 25.0.

3. Results

3.1. Floral Characteristics

Eschweilera tenuifolia flowers occurred in racemose inflorescences towards the ends of branches, and contained between 5 and 18 flower buds (mean \pm SD: 11.04 ± 2.83 , $N = 100$). The number of inflorescences per tree varied greatly (0 to 53 in 2007, mean \pm SD: 27.49 ± 15.52 , $N = 134$ trees), and showed little relation to tree canopy size ($r^2 = 0.6841$, $p = 0.00096$ for 2007 $r^2 = 0.7047$, $p = 0.584$ for 2008, $N = 15$) or DBH ($r^2 = 0.5979$, $p = 0.002$ for 2007; $r^2 = 0.5359$, $p = 0.565$ for 2008, $N = 15$) (Table 4; Figure 5). Generally, only one flower per inflorescence was open at a time: of 100 inflorescences, 82 had one, five had two, and three had three flowers open simultaneously. The number of inflorescences was also not consistent for individual trees between years (Table 4; Figure 5). Of the 12 trees for which data were available in both years, 11 had more inflorescences in the first year, showing a mean drop of $83.2\% \text{ SD} \pm 6.1$. This is consistent with strong biennial variation in reproductive investment (discussed below).

Table 4. Sequential year inflorescence number, diameter at breast height (DBH) and canopy surface area for *Eschweilera tenuifolia*.

Tree ID	DBH (cm) ¹	Canopy (Length \times Height, in m)	Canopy Curved Surface Area (m ²) ²	Number of Inflorescences in 2007/2008	Percentage Difference between Years
1	114	3.5 \times 1.5	19.23	46/13	−71.7

¹: rounded down when 0.1 to 0.49; rounded up when 0.5 to 0.99; ²: calculated as $2\pi r^2$.

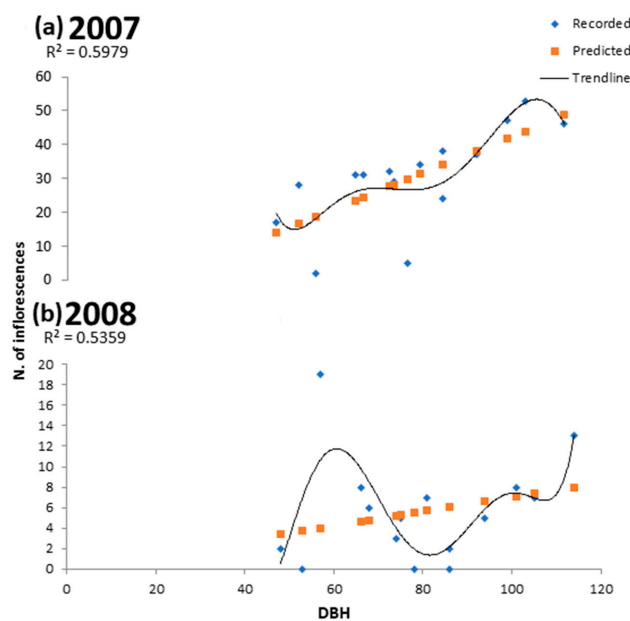

Figure 5. Number of *Eschweilera tenuifolia* inflorescences in sequential years for trees of differing diameter at breast heights (DBHs), Jaú National Park, central Brazilian Amazonia.

The mass of 100 complete, uninfested and fully-open flowers was 627.4 g, and the androecial hoods, when weighed separately, contributed 427.0 g (68.1%) of the mass. Mean flower dimensions were: 5.9 ± 0.3 cm from tip to tip of the two largest petals (range: 5.3–6.7 cm, $N = 100$); 1.9 ± 0.3 cm in length (range: 1.2–2.5 cm, $N = 100$); 1.5 ± 0.2 cm in height (range: 1.3–2.4 cm, $N = 100$); and 1.7 ± 0.3 cm (range: 0.8–2.4 cm, $N = 100$) in width for the androecium.

Inflorescence formation began in September, following leaf flush. However, speed of bud development varied between plants, with some becoming open flowers within 30 days and others taking 60 days or more.

3.2. Insect Predation

Infestation intensity: Of the 396 buds and 200 flowers, 58.8 and 73.0%, respectively, contained insect larvae. Within the tissues of 233 infested buds, we found a total 873 larvae from 10 different morphotaxa (3 Coleoptera, 5 Diptera, 2 Lepidoptera: mean no. individuals per bud (\pm SD), 3.74 ± 1.74 , range 1–9; mean no. morphotaxa per bud (\pm SD), 2.50 ± 1.10 , range 1–5). The 146 infested flowers had 394 individuals of four morphotaxa (2 Coleoptera, 1 dipteran, 1 lepidopteran: mean no. individuals per flower (\pm SD), 2.69 ± 0.65 , range 1–4; mean no. morphotaxa per flower (\pm SD), 1.94 ± 0.80 , range 1–3). These infestation levels of buds and flowers were statistically different for the number of larvae ($\chi^2 = 11.50$, $df = 1$, $p \leq 0.001$). Mean (\pm SE) numbers of insect morphotaxa on buds and flowers were 2.50 ± 0.073 and 1.95 ± 0.066 respectively. The number of morphotaxa on buds was significantly greater than on flowers ($t = -5.27$, $df = 377$, $p < 0.001$).

Relative masses of plant/invertebrate material: In terms of comparative masses, the mean value for infested buds weight (all stages) was 5.53 ± 1.08 g (range: 4.1–6.65 g), with $17.93\% \pm 10.82$ (range: 7.30–32.00%) of this being insect larvae. For infested flowers, mean mass per whole flowers was 5.37 ± 0.147 g (range: 5.17–5.65 g), with infesting larvae comprising $11.17\% \pm 2.76$ (range: 5.80–16.30%) of a flower's weight. Both proportional and absolute masses of infesting insects changed during flower development, with the greatest values recorded in stage 3, before flowers began opening (stage 4; Figure 6).

Infestation intensity by bud size: Of the buds analyzed, 28.00% (43 of 150) of the small (stage 1) buds, 80.10% (98 of 121) of the medium (stage 2) buds, 88.60% (78 of 88) medium–large (stage 3) buds, and 37.00% (14 of 37) large (stage 4) buds were infested (though extents of infestation varied).

Within these size classes, these differences were significant ($\chi^2 = 54.58$, $df = 3$, $p < 0.001$). However, mean infesting insect mass was significantly lower in flowers than in buds, both overall ($H = 19.859$, $p < 0.01$), and when only large buds (stages 3 and 4) were used ($U = 3.706$, $p < 0.001$; $U = 2.24$, $p = 0.025$: for stages 3 and 4, respectively). In summary, we found support for the prediction that infestation would be high.

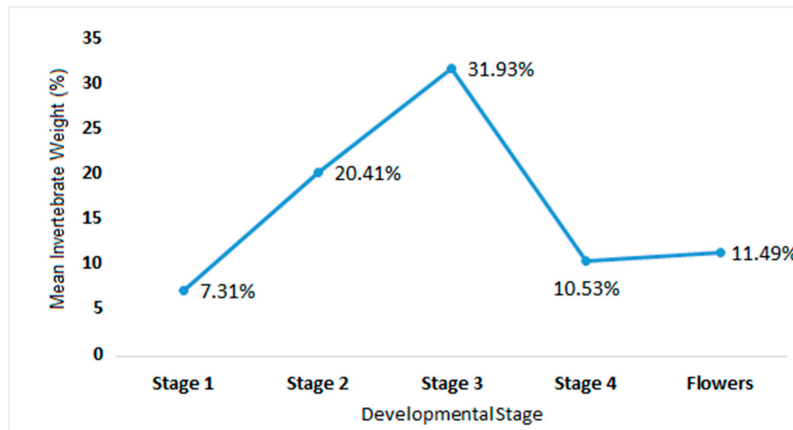

Figure 6. Mean proportional weight of invertebrates in developing buds and flowers of *Eschweilera tenuifolia*.

3.3. Flower:Fruit Ratios

In terms of the extent of damage of aborted and non-aborted buds, a total of 86 aborted buds (stage 1: 27, 31.4%; stage 2: 10, 11.6%; stage 3: 15, 17.4%; stage 4: 34, 39.6%) and 53 aborted flowers were collected and analyzed. Percentages of damage by damage class (light–heavy) for aborted and unaborted buds by developmental stage (stages 1–4) are given in Table 5. The percentage of aborted and non-aborted flowers by insect damage category is given in Table 5 (as stage 5). Damage level differed across size classes for buds that were aborted ($\chi^2 = 526.1$, $df = 12$, $p < 0.001$), and for buds that remained on the tree ($\chi^2 = 124.0$, $df = 12$, $p < 0.001$). While aborted buds generally had greater levels of damage when larger, there was no clear pattern for buds that remained on the tree; the smallest and the largest two size classes had the greatest percentage of their buds in the category of no obvious damage (Figure 7). In all, when the two lowest damage categories were combined, three of the four size classes for buds remaining on the tree had 90% or more of their samples in these two categories; the third size class had 75% of its samples in the two low-to-no damage classes. Comparatively, only the smallest size class of buds that were aborted (stage 1) demonstrated no obvious damage or light damage (Table 5).

Table 5. Degree of damage by infesting invertebrates on aborted and unaborted buds (Stages 1–4), and flowers (Stage 5) of *Eschweilera tenuifolia*.

Size Class (N)	A= Aborted U = Unaborted (from Tree)	Damage Category (N, % of class)				
		No Obvious Damage	Light	Medium	Medium-Heavy	Heavy
Stage 1 (27)	A	5 (18.5%)	15 (55.5%)	7 (26.0%)	0 (0.0%)	0 (0.0%)
Stage 2 (10)	A	0 (0.0%)	0 (0.0%)	8 (80.0%)	2 (20.0%)	0 (0.0%)
Stage 3 (15)	A	0 (0.0%)	0 (0.0%)	0 (0.0%)	11 (73.0%)	4 (27.0%)
Stage 4 (34)	A	0 (0.0%)	0 (0.0%)	2 (5.9%)	17 (50.0%)	15 (44.1%)
Stage 1 (150)	U	107 (71.3%)	39 (26.0%)	4 (4.7%)	0 (0.0%)	0 (0.0%)
Stage 2 (121)	U	23 (19.0%)	86 (71.1%)	12 (9.9%)	0 (0.0%)	0 (0.0%)
Stage 3 (88)	U	10 (11.4%)	56 (63.6%)	20 (22.7%)	2 (2.3%)	0 (0.0%)
Stage 4 (37)	U	23 (62.2%)	10 (27.0%)	3 (8.1%)	1 (2.7%)	0 (0.0%)
Stage 5 (53)	A	3 (5.7%)	15 (28.3%)	26 (49.1%)	7 (13.2%)	2 (3.8%)
Stage 5 (200)	U	54 (27.0%)	127 (63.5%)	18 (9.0%)	1 (0.5%)	0 (0.0%)

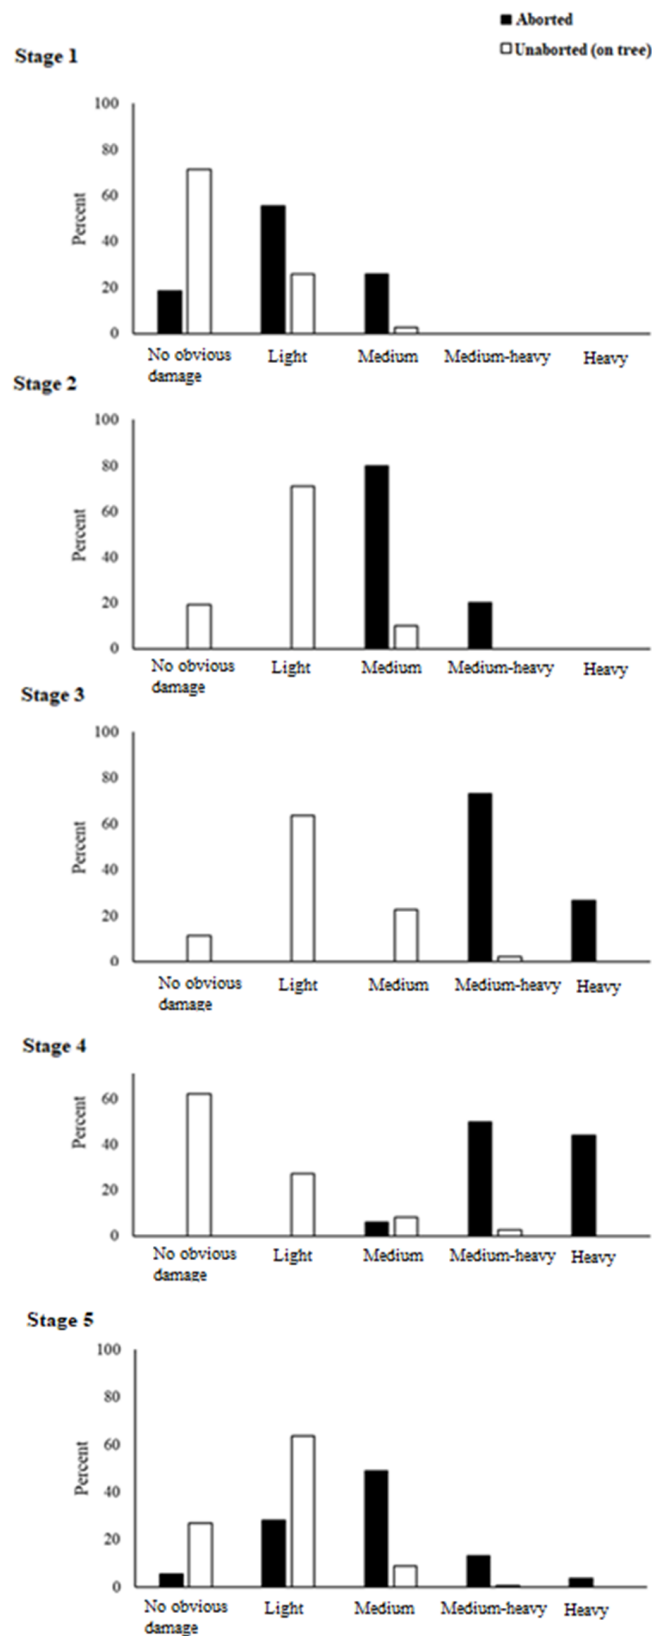

Figure 7. Bud damage percentage for the five developmental stages for fallen (aborted) buds and flowers, and on-tree buds and flowers (unaborteds): *Eschweilera tenuifolia*, Jaú National Park, central Brazilian Amazonia.

Overall, there was a pronounced difference between the extent of damage to buds that were aborted from the tree (and so were found floating on the water surface) and those that remained on the tree (and were thus considered unaborted) ($\chi^2 = 99.2$, $df = 4$, $p < 0.001$). For example, only 5.8% of the aborted buds showed no obvious damage, while 41.2% of the buds on the tree showed no obvious damage (Figure 7). When the aborted buds and those buds that had remained on the tree were compared within each of the four size classes, these differences held for each of the four size classes (stage 1; $\chi^2 = 56.49$, $df = 4$, $p < 0.001$; stage 2: $\chi^2 = 164.76$, $df = 4$, $p < 0.001$; stage 3: $\chi^2 = 191.08$, $df = 4$, $p < 0.001$; and stage 4: $\chi^2 = 176.10$, $df = 4$, $p < 0.001$).

The extent of damage also differed between flowers that had been aborted and flowers that remained on the tree ($\chi^2 = 70.26$, $df = 4$, $p < 0.001$). Only 5.8% of aborted flowers had no obvious damage, while 27.0% of the flowers on the tree showed no obvious damage (Figure 7, stage 5). In addition, on some study plants, up to 25% of flowers had 1 to 3 petals all or partially removed by leaf-cutter bees (Megachilidae).

Of the 134 trees in the study that flowered, 97.01% ($N = 130$) produced fruit. However, of these 130 trees, three trees died or suffered tree-fall damage during the study. Of the 635 inflorescences on the remaining 127 trees, 5.83% ($N = 37$) disappeared during the monitoring process. Thus, calculations were based on 598 inflorescences and the single flower monitored on each of these inflorescences. In total, 3.5% (21 of 598) of marked flowers produced fruits that reached the button stage of development. Since testing for infestation was destructive, it was not possible to say whether flowers that did not produce fruits were infested with insect larvae or not. However, the percentage of aborted stage 3 and stage 4 buds with internal damage levels categorized as 'high', was significantly higher than those remaining on the tree (Figure 7, stage 5). For flowers, significantly more aborted flowers showed damage to anthers than did flowers that were removed from the tree for analysis (Figure 7). Thus, while we cannot offer direct evidence that the flowers that developed into fruits were uninfested, or only lightly infested, and those failed to produce fruits had heavy infestation and were aborted, we believe that this is a reasonable inference from the available data.

3.4. Pollen Predation

Thrips, mites, aphids or staphylinid beetles were present in 1.8% ($N = 7$) of buds, and 49% ($N = 98$) of flowers; there was a statistical difference between infestation levels of buds versus flowers ($\chi^2 = 201.56$, $df = 1$, $p < 0.001$). In the flowers, the great majority (not counted, but visually estimated at over 80%) were found on the infertile 'fodder pollen' of the adroecial hood. Thrips from two families (Phlaeothripidae and Thripidae) were identified, although 30% remained unassigned.

3.5. Nectar Production

A total of 720 flowers were sampled in daylight and 53 at night. There were strong peaks in nectar production between 06.30 and 10.00 h. Little or no production occurred after 13.00 h and none between 15.00 and 18.00 h. None of the flowers collected after dark showed any evidence of nectar production (Figure 8). Brix sucrose levels averaged $37.4\% \pm 3.65$ (range: 29–44%, $N = 275$). With zero values removed, nectar volumes varied between 10 and 560 μL (mean 171.7 μL , $SD \pm 125.2 \mu\text{L}$, $N = 322$ (Figure 9). Temporal variations in both sugar concentration and nectar volume were observed (Figures 8 and 9), with low initial volumes and concentrations very early in the morning, presumably before photosynthetic products were available for mobilization, after which levels largely stabilized until a rapid decline in the early afternoon. There was no recorded nectar production at night (Figure 8).

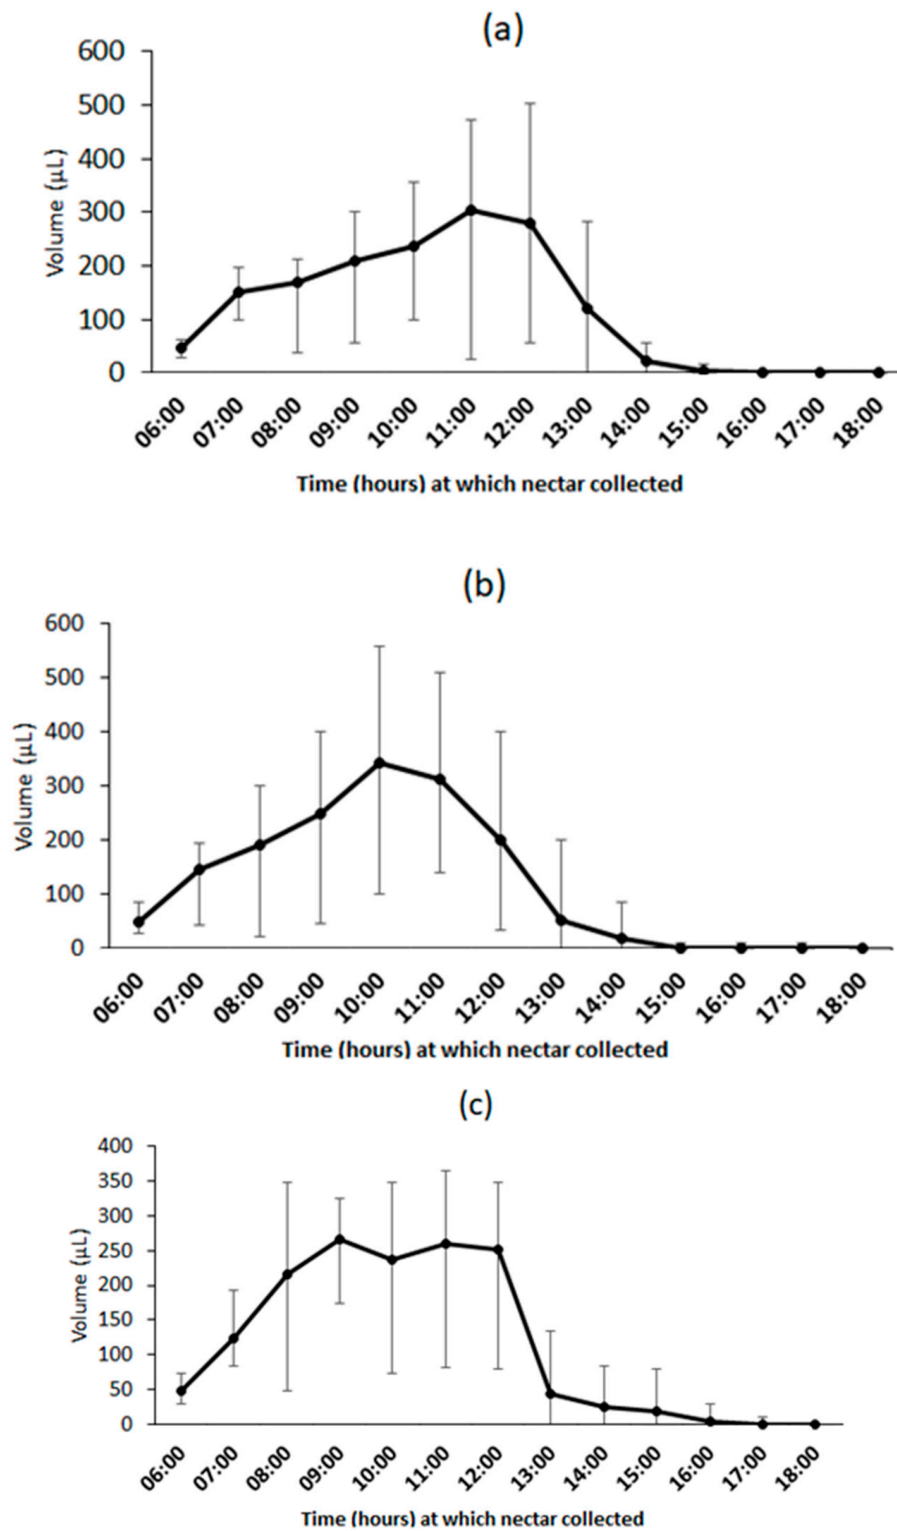

Figure 8. Diel variation in mean \pm SD nectar volumes for first three days of flowering: (a) = day 1, (b) = day 2, (c) = day 3.

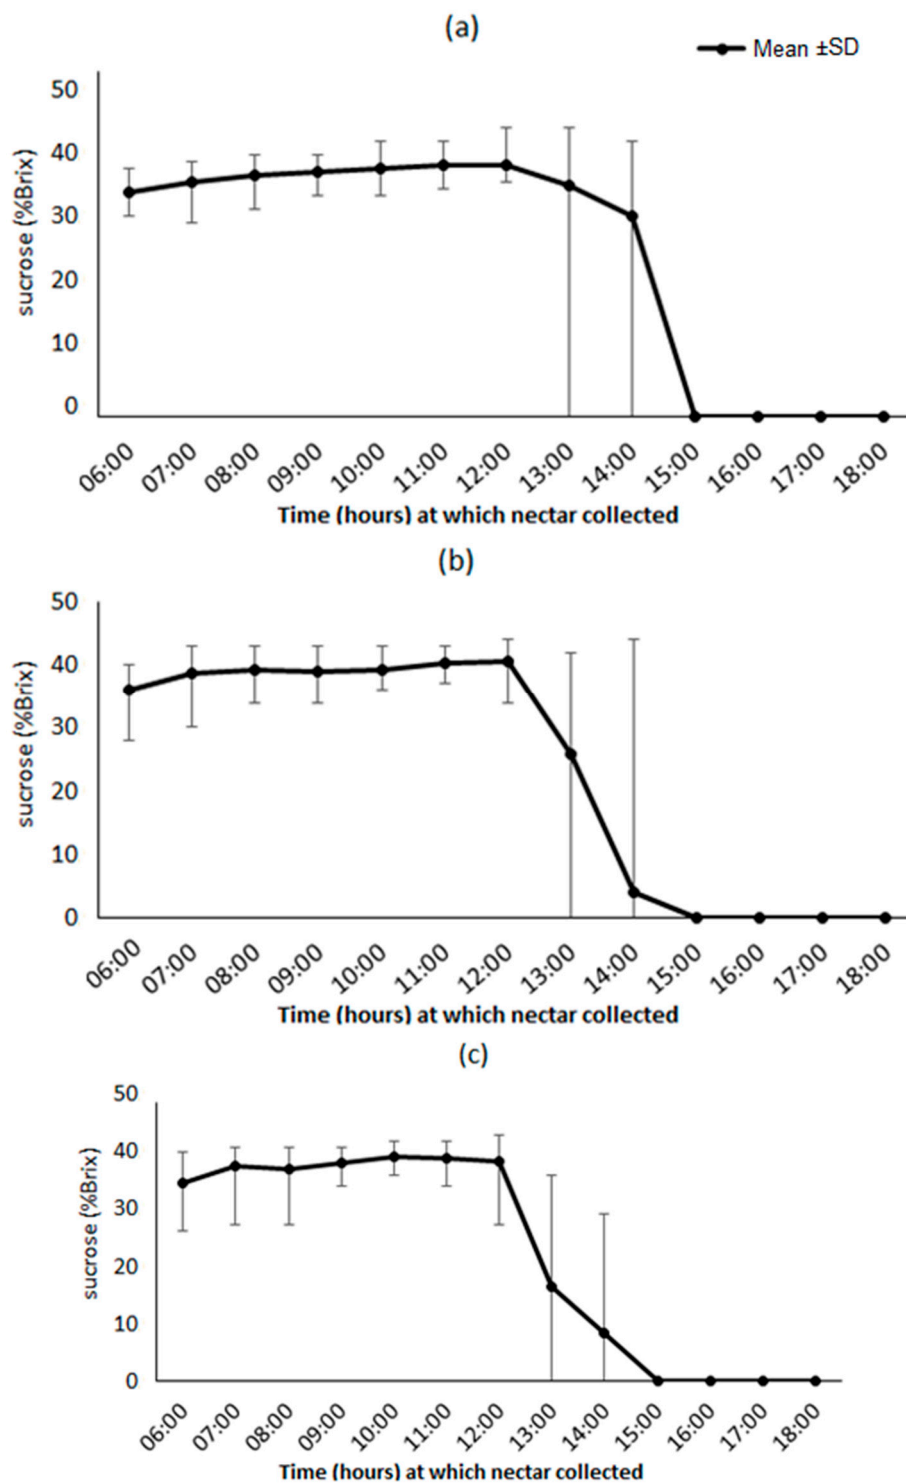

Figure 9. Diel variation in nectar concentrations for first three days of flowering (mean \pm SD): (a) = day 1, (b) = day 2, and (c) = day 3.

4. Discussion

Levels of fruit set in *Eschweilera* are generally low (e.g., 0.0036% [65]), and this appears common in the family, having been observed for other genera within the Lecythidaceae, e.g., 0.4% for *Betholletia* [72,94] (*Couroupita* [95]; *Lecythis* [96,97]). Therefore, it is curious that levels reported in the current study were much higher (21/598: 3.5%), especially since soil nutrient poverty [59] and energetic limitation [59] have been advanced as explanations for low fruit set in species living in habitats

that are far less challenging than the *igapó* inhabited by *E. tenuifolia*. However, the result may be a methodological artefact, since previous studies did not specify the developmental stages at which study fruits were enumerated. In our study, since we aimed to avoid the impact of predation by vertebrate seed predators during a study of the impact of invertebrate bud predators on fruit set, counting was paused at an early stage in pyxidial development. Though methodologically valid, our methods may have led to higher values being tallied, thereby limiting comparisons with earlier studies, which would have included the later, larger, stages at which vertebrate predation typically occurs. In addition, hand-pollination of *E. ovata* gave 85% fruit set [64], suggesting that other factors, such as pre-pollination abortion of flowers, may be involved in the low fruit set values otherwise observed.

Commercial crop reduction is often impacted by insect infestation of flower buds [98–100], and this may also occur in *E. tenuifolia*. The highest proportion of infested buds was found in stage 3 (medium/large). Stage 4 (large), the stage at which petals would unfurling, had fewer infested buds than the immediately preceding stages. This may be related to the high rate of bud abortion observed prior to flowers opening to attract pollinators. This has been found to occur by other plants as a response to bud infestation [101–104], and it may be common in Lecythidaceae: bud infestation and low rates of fruit set have been noted in previous studies [59,60,65]. Lecythidaceae flowers generally have very well-defined abscission plates [105], and abortion of insect-infested buds has been recorded in some members of the family (*Eschweilera bogotensis* [59]; *Napoleonaea vogelli* Hoolv. [106]). In any case, flower:fruit ratios in Lecythidaceae appear to be low compared to those of other tropical trees, and in the range of values of species where these ratios are considered low (*Myristica insipida* R.Br. Myristicaceae, 1% [107]; *Grevillea* spp., Proteaceae, 0.015–0.096 [108]).

Mean infesting insect mass was significantly lower in the flowers than buds, both when all four bud stages were considered and when only large buds (stages 3 and 4) were used. The proportion of infested buds also dropped dramatically between stages 3 and 4. From this, the plants appear to be selectively aborting infested buds, a well-known response to infestation [102,109]. The subsequent rise in percentage infestation in flowers is likely due to a second wave of infestation, with either (i) the maturation at the flower stage of many small larvae laid at the bud stage, but not seen or (ii) infestation and rapid growth of larvae in flowers once open. As the larvae of the beetles studied by Udovic [109] require a week to develop in a bud, and bud-infesting moths appear to require a similar minimum [110], option (i) is perhaps the most likely. However, both mechanisms would give a two-phase infestation pattern, so that further work is required to discover which is in operation.

The notable change between stages 3 and 4 in the proportion of the mass of the bud represented by infested insects and by the proportion of buds that were infested indicates that buds grew up to a point (stage 3) and then, if infested, tended to be aborted after this. Thus, flowers that opened were those that were either (i) uninfested or (ii) had insufficient infestation to trigger abortion responses by mother plant (which are generally chemically-mediated and have critical threshold levels [111,112]).

Distribution of damage categories as the buds developed showed likely early abscission of uninfested buds in stage 1 (Figure 7) as a means of reducing on-inflorescence competition between fruits [113], as well as the trend for proportional increases in infestation as buds mature (Figure 7, stages 2–4). The overall impact of insect damage on bud abortion may be seen in the over-representation of stage 4, in the sample of aborted buds. Aborted flowers were significantly more heavily infested than flowers on trees. Thus, it appears that infestation of buds and flowers can reduce the number of locations for pollination (and perhaps the number of flowers that have been pollinated that can go on to develop fruits), which, overall, contributes to lower fruit set and reduced flower:fruit ratios. Indeed, as noted by Herrera et al. [114], fruit set is pollen limited in many animal-pollinated plants, so that there may often be more flowers available than can be visited and pollinated by local pollinator populations.

There may be some bias as, when floating, more heavily infested buds and flowers may have been eaten preferentially by fish (many *igapó* fish using allochthonous materials due to low aquatic system productivity [115,116]). While this would only have occurred once *igapó* was well-flooded,

it may have caused underestimation of heavily infested categories. Additionally, the damage categories were deliberately broad to guarantee reasonable numbers for statistical analysis. However, as a result, finer patterns may have been obscured. This could be resolved with larger samples and more precise damage percentage categorization. Additionally, it is acknowledged that, in later stages, it is not possible to be certain whether observed damage resulted from recent insect activity, or whether it is the result of smaller-sized activities whose dimensions have grown as the bud expanded. However, either way, if the overall fitness of the organ as a reproductive module is impeded (by herbivory, for example), this may be what determines whether the bud or flower is aborted or not [117,118].

In terms of energy balance, rapid detection and subsequent abscission of infested buds is favorable for the overall reproductive success of an individual plant, as a flower resulting from an infested bud may be inviable due to anther [109] or ovary damage or removal [119]. Further, a flower may not attract pollinators if, as a result of larval action [120,121], lacks nectar or other products that attract pollinators once the infesting larvae have destroyed the nectar-producing glands [122,123]. These, together, can result in the attraction of fewer pollinators and/or setting fewer seeds.

Future studies should investigate if bud infestation has an adaptive component, since having some already infested buds may protect the uninfested buds, by making them (a) the few among many, and so harder to find—possibly triggering search abandonment by egg-laying females via implementation of optimal giving-up time strategies; (b) increasing the chance that, if female invertebrates do lay eggs, that they will deposit on a bud that is already occupied and so not impact currently uninfested buds; (c) reduce the chances attack by parasitoid wasps, since larger, already present, larvae are more likely to be detected and/or encountered by prey-seeking wasps. Alternatively, it may be that insect larvae secrete chemicals that disrupt the plant response systems into responding as though there is no threat (“thinking that all is well” [124]). By virtue of the size and abundance of the flowers, the *E. tenuifolia* flower/insect system allows investigation of such subtle interactions, and so further investigation is encouraged.

Thrips, small beetles and other potential pollen predators were almost entirely absent from buds. Therefore, we found support for the prediction (prediction 3) that visitation of anthers by pollen predators would occur only once flowers had opened and access was facilitated. Levels of flower infestation by thrips, mites and staphylinid beetles was fairly high (49%) in the current study. All these invertebrate taxa contain members that are known predators of pollen [125–127]. However, without detailed studies, it is not possible to be certain that this was the case here (though it must be considered very likely). If they were predators, then the higher rates of mite and thrip infestation on the upper, infertile, anthers may indicate that such pollen functions sacrificially, reducing the loss of fertile pollen. However, other studies of Lecythidaceae mention mites and thrips present in and between anthers [95,128], and the relative proportions of distribution between the two anther types may do no more than reflect their relative surface areas. However, it is clear that the buds have very low levels of thrip, mite, aphid and staphylinid infestation, which is likely due to the mechanical difficulty they would face in entering a closed bud unaided, since most species of such pollen predators are phoretic [129,130], and so would be unlikely to colonize a flower until pollinators can visit it. In terms of pollen loss to thrips, while Thripidae includes many pollen feeders, the majority of Phlaeothripidae species are fungus feeders or carnivorous [89,90]. Thus, at least a proportion of the thrips present may have been feeding on yeasts, rather than pollen, or the other thrips, mites and aphids inhabiting the flowers at the time.

Petals are one of the many materials used by megachilid bees to line nest brood cells [131]. However, the effect of megachilid bee petal removal on pollinator visitation and pollination success in *E. tenuifolia* was not investigated in the current study. But, given the well-established influence of flower size these aspects of floral biology [132,133], and flower damage [134,135], it would not be surprising if there were effects to be documented. The system clearly lends itself to experimental manipulation [136], and could be an interesting subject for future study.

The pattern of sucrose concentration and nectar volume recorded here parallels that recorded for *E. nana* [65], with rapid rises in levels in the early morning and swift declines in the early afternoon. Neither of these resembles the pattern recorded for *E. ovata* [64], which showed a distinct midday peak. Purely diurnal patterns of nectar production confirming diurnal pollination, while patterns of nectar production (in both volume and sucrose content), This provided support for the prediction (prediction 4) that nectar production would occur during daylight hours, and would be constant across the production period.

Mean sucrose levels of 37.4% recorded here are close to those reported for *E. coriacea* (DC.) S.A. Mori (36% [137]), *E. ovata* (36.4% [64]), and *E. nana* (30.7% [65]); all are in line with the 30–40% concentration considered biomechanically optimal for suction-feeding Euglossine bees [138]. Prance [58] reported that visits by xylocopid bees to *Eschweilera* trees occurred between 08.30 and 10.00 hrs. Although the data were recorded in *terra firme* species of *Eschweilera*, it still matches the patterns we recorded. Indeed, it appears that the timing of nectar production can be remarkably consistent between congeneric species across habitats when, as here, the form of pollinator remains the same [139,140]. Mean nectar volumes recorded here ($171.7 \pm 125.2 \mu\text{L}$) are also similar to those recorded for the similar-sized flowers of *E. nana* ($196.5 \pm 102.4 \mu\text{L}$ [65]). Values in the current study may be lower due to the presence in the data set of very low values (10–40 μL), possibly associated with measurements being conducted immediately after a nectar removal event by a pollinator. If such values below 99 μL for days 1–3 are removed from the 324 records from 06.00 to 14.00 ($n = 114$, 35.2% of all records), the mean rises to 241.7, $\text{SD} \pm 97.37$.

The duration of flowers (4–5 days) is unusually long for the neotropical Lecythidaceae which, according to Mori and Prance [3] “open their flowers early in the morning and drop their petals and androecia in the same afternoon”. However, while *E. ovata* flowers may also last but a single day [64], other members of the genus *Eschweilera* do not follow this pattern, as flowers generally last 2–3 days (*E. grandiflora* (Aubl.) Sandwith and *E. pedicellata* (Rich.) S.A. Mori [57]; *E. nana* [65]); though *E. ovata* flowers may last but a single day [64]). The extension of individual flower life to 5 days in *E. tenuifolia* may be a means of maximizing likely reproductive gains in an energy-limited system. This may help explain the higher levels of seed set noted in *E. tenuifolia* compared to other species. However, this may itself be a compensatory mechanism for the fact that *E. tenuifolia* is hydrochorous [35], and so may be expected to suffer high levels of seed mortality during dispersal [141–143]. Whether this, itself, is offset with reduced investment in pyxidial wall thickness will be the subject of a future study.

As noted by Janzen [144], direct consumption of flowers can lower seed crop size, but the relationship of flower crop size to seed crop size may not be especially tight. Many plants produce large numbers of flowers only to attract pollinators, and as a plant can perceive the loss of a flower, there may be some compensatory flower production. Nevertheless, the high flower:fruit ratios and large crop volumes of *E. tenuifolia* are surprising, especially considering how challenging it appears to be for plants to live in *igapó* [145], particularly in sites where flooding can last for 7 to 8 months, as is the case with *E. tenuifolia* [51,146,147]. However, partial compensation for this stress may be the deployment by *E. tenuifolia* of a strategy of near-biennial flowering, such that each plant has a heavy flowering year, followed by a light one (AA Barnett and WS da Silva-Carneiro, unpublished). Such a supra-annual flowering also occurs in other *igapó* tree species, including *Aldina latifolia* Spruce ex Benth and *Cieba pentandra* (L.) Gaertn. [74], as well as other members of the genus *Eschweilera* (e.g., *E. tetrapetala* S.A. Mori [63]). This form of phenology could allow individual plants to maximize effective energy investment in reproduction, both in terms of attractiveness to pollinators, and as a means of diminishing proportion of (energetically-demanding) produced seed crop lost to seed predators. This is known from several other *igapó* species, including *A. latifolia* Spruce ex Benth. and *C. pentandra* [74]. This set of adaptations allows for successful colonization by *E. tenuifolia* in this extreme ecosystem and will be the subject of future studies.

5. Conclusions

Insect infestation of buds can play an important role in regulating flower:fruit ratios, thus setting limits on individual total seed set. Individual *E. tenuifolia* appear to invest highly in reproduction every second year. Extended flower duration (up to 5 days, rather than 1 day as common in the genus) may be a strategy to enhance pollination success, but it also increases overall reproductive investment via continued nectar production. Abortion of heavily infested buds may minimize allocation of energy to otherwise malformed flowers, which are likely to have lower chance in attracting pollinators. Such a strategy functions to save energy in the short term. Additionally, biennial peaks of investment in flowering by individual *E. tenuifolia* are likely to be an energy-conserving response in a highly physiologically-challenging environment. Thus, *E. tenuifolia* exhibits energy-conservation strategies at two divergent temporal scales.

All authors have read and agreed to the published version of the manuscript.

Funding: Funding was provided by the American Society of Primatologists, the Columbus Zoo Conservation Fund, the Sophie Danforth Conservation Fund, the LSB Leakey Foundation (US), the Leakey Fund (UK), the MIL Fund (Laurie Shapley), the Margot Marsh Foundation, the Oregon Zoo Conservation Fund, the Percy Sladen Memorial Fund, the Pittsburgh Zoo and Aquarium Conservation Fund, the Primate Action Fund, the Primate Conservation Inc., the Primate Society of Great Britain, Roehampton University, and the Wildlife Conservation Society (all to A.A.B.). B.M.B. was supported by a University of Bristol ORS grant, the Rufford Foundation and Idea Wild at the time of data collection. M.T.F.P. acknowledges PELD-MAUA (CNPq/FAPEAM) for financial and infrastructural support. A.A.B. is currently a CAPES-APNS grant holder (code 001), and B.M.B., is supported by CNPq productivity grant 309256/2019-4 and by FACEPE grants APQ 0143-2.04/14; BTF-0160-2.04/17 and BTF-0014-2.05/20.

Acknowledgments: We dedicate this paper to Scott Mori (1941–2020), in recognition of his extraordinary work with Lecythidaceae, and to mourn his recent passing. We thank Eduardo do Souza and Roberto Moreira, Maria do Jesus, field guides for the Jaú component of the study; Rebecca L. Shapley and Welma S. da Silva Carneiro for botanical field help; Daniel Praia and Naara Ferreira da Silva for sharing images. Fabricio Baccaro identified the ants, Mike Hopkins identified the beetles and John Wetzel identified the wasp nest. This is Contribution # 54 from the Amazon Mammals Research Group, and # 40 from the Igapó Study Project.

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the results.
