**Abstract:** Recent remote sensing studies have suggested exploiting vegetation optical properties for assessing oil contamination, especially total petroleum hydrocarbons (TPH) in vegetated areas. Methods based on the tracking of alterations in leaf biochemistry have been proposed for detecting and quantifying TPH under controlled and field conditions. In this study, we expand their use to airborne imagery, in order to monitor oil contamination at a larger scale. Airborne hyperspectral images with very high spatial and spectral resolutions were acquired over an industrial site with oil-contamination (mud pits) and control sites both colonized by *Rubus fruticosus* L. The method of oil detection exploiting 14 vegetation indices succeeded in classifying the sites in the case of high TPH contamination (overall accuracy  $\geq 91.8\%$ ). Two methods, based on either the PROSAIL (PROSPECT + SAIL) radiative transfer model or elastic net multiple regression, were also developed for quantifying TPH. Both methods were tested on reflectance measurements in the field, at leaf and canopy scales, and on the image, and achieved accurate predictions of TPH concentrations (RMSE  $\leq 3.28$  g/kg<sup>-1</sup> and RPD  $\geq 1.90$ ). The methods were validated on additional sites and open up promising perspectives of operational application for oil and gas companies, with the emergence of new hyperspectral satellite sensors.

## 1. Introduction

Since the beginning of the 20th century, oil and gas supply has constantly increased to satisfy a growing demand worldwide [1,2]. Along with the development of the oil industry, important efforts have been made to mitigate the associated environmental risks [3–5]. Oil spills and leakages are of major concern in the onshore domain. They are likely to occur at every step of the production process (i.e., oil extraction, refining, and transportation) contaminating the soil and groundwater and remaining as mud pits after their cessation [6–8]. The resulting soil contamination causes important ecological alterations (e.g., landscape fragmentation and habitat loss) [9–12]. To avoid such consequences, fast and accurate detection and quantification of oil contamination are, therefore, necessary.

Total petroleum hydrocarbons (TPH) are good indicators of oil contamination in soils [13,14]. They are the main constituent of oil and show high toxicity toward organisms. (In this study, the terms

oil and TPH were used indifferently.) Among the methods proposed for detecting and quantifying TPH contamination, hyperspectral remote sensing has become a promising one [15,16]. Recent advances in this field allow monitoring industrial facilities (e.g., pipelines and storage tanks) at a large scale using airborne or satellite imagery [17,18], however, this approach is based on the detection of apparent oil at the surface, so its application in vegetated regions remains impossible. This causes a critical issue in regions with dense vegetation and intensive oil production activities. In this context, alternative approaches based on exploiting vegetation optical properties have emerged during the last decade [8,19–22].

TPH induce strong alterations in leaf anatomy and biochemistry related to their optical properties in the reflective domain (400–2500 nm) [23–27]. These alterations lead to modifications in the spectral signature of vegetation and suggest being able to detect oil in vegetated areas using optical remote sensing [28–30]. On the basis of this assumption, a few studies have attempted to map oil spills and leakages using multi- and hyperspectral airborne or satellite imagery with four to 30 m spatial resolution (mainly Landsat, Hyperion, and Hymap systems) [8,19,31,32]. Most of them have relied on comparisons of vegetation indices between healthy and contaminated sites, but only a few have proposed a method to detect oil contamination automatically, and even fewer have evaluated its performance. In addition, none of these studies attempted to quantify TPH. In most cases, the method of detection was applied to entire images [19,32]. This gave rise to the apparition of false alarms, caused by differences in species' sensitivity to oil, bare soil-mixed vegetation pixels, and the presence of other vegetation stressors (e.g., water deficit). False alarms have been more pronounced using multispectral satellite imagery. Thus, several conclusions emerged from these studies. First, very high spatial (1–2 m) and spectral (<10 nm) resolutions are needed to achieve accurate detection of oil. Then, prior application to entire images, i.e., it is necessary to calibrate the methods over restricted areas with known species and contamination. Then, the methods should be validated on spatially independent sites with the same species and, as a last step, applied to entire images, provided that the target species' location is known.

Species established around industrial oil facilities are naturally tolerant to soil contamination and difficult to distinguish from healthy vegetation [33,34]. It is, therefore, challenging to develop methods for detecting and quantifying TPH adapted to these species and intended to be applied to airborne and satellite hyperspectral images. Detecting and quantifying TPH is even more difficult in the presence of other environmental factors (e.g., water deficit). As suggested in previous work, this could be achieved by experiments carried out under controlled conditions [28,35]. Several studies have aimed to characterize the effects of oil on vegetation reflectance under controlled conditions [29,36–38]. Vegetation indices and spectrum transformations (first and second derivatives, continuum removal) have been frequently used for this purpose [20,30,38–40]. The wavelengths linked to pigment and water contents were particularly suitable for distinguishing healthy and oil-exposed vegetation with no or minor confusion [21,34]. More recently, Lassalle et al. [28] succeeded in discriminating among various types of oil contamination at leaf and canopy scales using vegetation indices. The same approach performed well for detecting mud pits contaminated by TPH in the field, by exploiting the reflectance of an oil-tolerant species (*Rubus fruticosus* L.). Radiative transfer models also sparked great interest for tracking alterations in leaf pigment contents caused by oil. For example, Arellano et al. [41] inverted the PROSPECT model [42] to detect changes in leaf chlorophyll content (LCC) resulting from an oil spill under tropical region. The same model was recently used for quantifying TPH in mud pit soils from leaf reflectance measurements performed in the field [43]. As suggested, its coupling with the SAIL canopy model [44] (forming the PROSAIL model [45]) might be of great interest for quantifying oil contamination in vegetated areas, from hyperspectral images. This challenge remains, however, very difficult, as it implies being able to track subtle changes in LCC from airborne or satellite sensors.

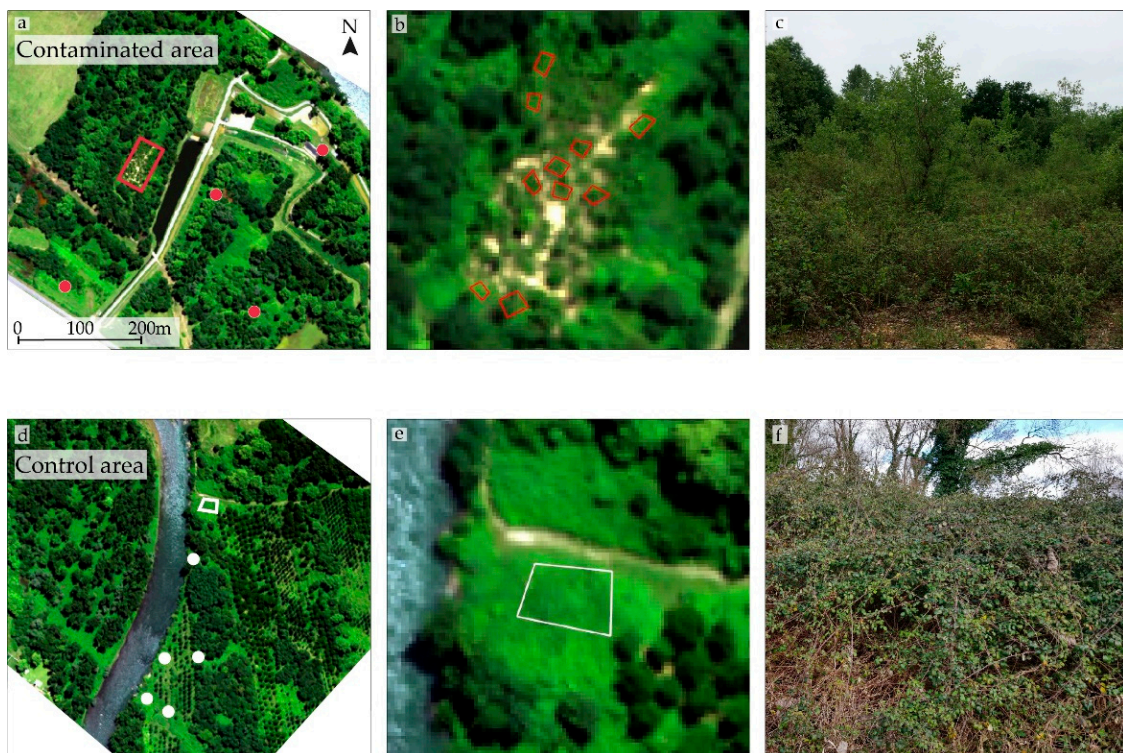

In the continuity of the abovementioned studies [28,43], this work aims to detect and quantify oil contamination (i.e., soil TPH content) in vegetated areas using airborne hyperspectral images with very high spatial and spectral resolutions. To achieve this, a method of detection previously developed under

controlled conditions, hereafter summarized, was first applied to the images. Then, two approaches, either PROSAIL or multiple regression, are proposed to quantify TPH. Both were assessed in the field and on airborne hyperspectral images, on selected vegetation patches with known species.

## 2. Materials and Methods

### 2.1. Study Area and Soil Sampling

The study was carried out in a temperate region, on an industrial area subject to important oil and gas activities. During the past 50 years, oil production residues were accumulated in mud pits, which resulted in contamination of soil by TPH. Some of these mud pits remain and have been colonized by oil-tolerant vegetation, mainly *Rubus fruticosus* L. (bramble) (Figure 1c). The study focused on this species, as it is generally well-established in temperate industrial areas. Bramble served for developing the methods of oil detection and quantification under controlled and field conditions [28,34,43] and was suitable for application to hyperspectral imagery.

**Figure 1.** (a,d) Subsets of the airborne hyperspectral image acquired over (a) the contaminated and (d) the control sites. The calibration sites are illustrated by polygons. Circles correspond to the validation sites (red: contaminated, white: control). (b,e) Zoom on (b) the brownfield (10 plots) and (e) the control sites used for calibrating the methods, respectively. (c,f) *R. fruticosus* on (c) the brownfield and (f) on the control site in March.

Five mud pits were identified for the study (Figure 1a), and the largest one (approximately  $40 \times 100$  m, hereafter described as “brownfield”) was used for calibrating the methods. Within this site, 10 homogeneous and spatially correlated plots of 16 to  $20 \text{ m}^2$ , mainly covered by *R. fruticosus* (>95%), were defined in the field (Figure 1b). Their geographical coordinates were acquired, and soil analyses were performed in two locations of each plot. Analyses revealed  $\text{C}_{10}\text{-C}_{40}$  TPH concentrations ranging from 17 to  $39 \text{ g/kg}^{-1}$  on the site. The same sampling procedure was carried out on the four other mud pits, which were not spatially correlated with the brownfield. A single plot was defined on each of them, since they occupied a much smaller area. One of these mud pits exhibited comparable TPH concentrations ( $24 \text{ g/kg}^{-1}$ ) (Table 1) and low concentrations were found in the other mud pits

( $\leq 3.15 \text{ g/kg}^{-1}$ ). More information about the mud pits, including soil properties, can be found in our previous studies [28,34,43]. In addition, one large ( $\sim 20 \times 20 \text{ m}$ ) and five smaller control sites colonized by *R. fruticosus* were identified in the same region and used for the calibration and validation of the detection method, respectively, Figure 1d–f. No TPH were detected in soil analyses for any of the control sites. These sites, however, differed slightly in soil properties, especially in texture and the surrounding ecosystem (poplar plantation, grassland, and riparian forest). They were thus suitable for assessing the robustness of the method of detection.

**Table 1.** Description of the sites used for testing and validating the methods. (<DL, below detection limit).

Step	Zone Type	Number of Zones (n)	Total Pixel Count	C <sub>10</sub> -C <sub>40</sub> TPH (g/kg <sup>-1</sup> )
training + test	control	1	388	<DL
training + test	mud pit ("brownfield")	10	184	17–39
validation	control	5	211	<DL
validation	mud pit	4	33	0.25
			20	0.38
			48	3.15
			22	24

## 2.2. Hyperspectral Data Acquisition and Preprocessing

### 2.2.1. Airborne Images

Hyperspectral images were acquired over the study area on July 5, 2017 at 1:15 p.m., at 2103 m above sea level in the absence of cloud, using airborne VNIR-1600 and SWIR-320m-e HySpex cameras (Norsk Elektro Optikk AS, Lørenskog, Norway) (Figure 1a,d). These images had a spatial resolution of 1 and 2.5 m and a spectral resolution of 5.2 and 7.8 nm in the visible-near infrared (VNIR, 400–1000 nm) and short-wave infrared (SWIR, 1000–2500 nm) domains, respectively. The SWIR image was resampled to 1 m spatial resolution using a nearest neighborhood filter, in order to preserve the spatial information, and registered according to the VNIR image using the Gefolki algorithm [46]. The resulting spectral radiance image was then converted to spectral reflectance using the empirical line method (ELM) [47,48], because of the lack of knowledge about the composition of the local industrial atmosphere. This provided a 1 m resampled reflectance image with 409 spectral bands covering the reflective domain (400–2500 nm). Because of the low signal-to-noise ratio (SNR), we did not conserve the bands with atmospheric transmission below 80%, as described in [49]. A Savitzky–Golay smoothing filter [50] was applied to improve the SNR at the remaining bands, and the final 1 m georeferenced reflectance image was used for calibrating and validating the methods of detection and quantification described hereafter.

### 2.2.2. Field Reflectance

On the day of image acquisitions, a field campaign was carried out on the 10 plots of the large mud pit ("brownfield") (Figure 1b). On each plot, 18 and 9 spectral signatures of brambles were acquired at leaf and canopy scales, respectively, using an ASD FieldSpec 4 Hi-Res spectroradiometer (Malvern Panalytical, Malvern, UK). Data were acquired in radiance between 11:30 a.m. and 2:00 p.m. and converted to reflectance, as described in [28]. Leaf measurements were performed with a leaf clip. Canopy reflectance was acquired using a 25 mm wide fore optics placed 45 cm above the target at nadir, providing a 20 cm wide acquisition footprint. All spectral signatures were then resampled to the spectral resolution of the airborne image and the same band removal and smoothing procedures (atmospheric transmittance <80% and Savitzky–Golay smoothing filter) were applied. These data were used for calibrating the method of TPH quantification.

### 2.3. First Step of the Approach: Detection of Oil Contamination

A comprehensive flowchart of this study is presented in Figure A2 in the Appendix A. The approach proposed in this study is divided into the following two successive steps: (1) the detection of oil contamination and (2) the quantification of TPH. The first one relies on the application of a method previously developed in the same context of study, under controlled conditions. The method exploits 14 vegetation indices, computed from the spectral signatures, and the  $L^2$  regularized logistic regression (RLR) [51] classifier to determine whether vegetation is, or has been, exposed to oil (see [28] for a detailed description of the method). These indices have been linked to the effects specifically induced by oil on leaf pigment and water contents of bramble. They are listed in Table A1 in the Appendix A. The method succeeded in detecting oil contamination under controlled conditions, at leaf and canopy scales [28]. It has been validated under natural conditions on the brownfield, and therefore, in this study, we focused on its application to the airborne hyperspectral image.

The method was first tested on the 10 plots of the brownfield and on the large control site (Figure 1b,e). The corresponding spectral signatures were extracted from the image and the 14 vegetation indices were computed. Data were split into 50% training and 50% test sets using the Kennard–Stone algorithm [52], with an equal proportion of pixels from the brownfield and the control site in each. The RLR classifier was fitted on the training set and applied to the test set. Predictions made on the test set were evaluated using the overall accuracy (OA), Cohen’s kappa coefficient, and confusion matrices [49,53,54]. The method was then validated on the other contaminated and control sites ( $n = 4$  and 5 sites, respectively, Table 1).

### 2.4. Second Step of the Approach: Quantification of Soil TPH Content

#### 2.4.1. First Method Based on PROSPECT and PROSAIL

The first method proposed for quantifying soil TPH content relies on the retrieval of LCC by inverting the PROSPECT and PROSAIL radiative transfer models [42,44,45]. The PROSPECT model simulates the hemispherical reflectance and transmittance spectra of leaves in the reflective domain, knowing their biophysical and biochemical parameters (listed in Table 2). The model can be inverted to retrieve these parameters from reflectance measurements, using an iterative optimization approach [55,56]. The latter consists in successively testing different sets of parameters (denoted by the vector  $\theta$ ) and retaining the one that best simulates the measured spectral signature [57,58]. This is achieved by minimizing the cost function  $J$ , defined as:

$$J(\theta) = \sum_{\lambda_{\min}}^{\lambda_{\max}} (R_{\text{meas}}(\lambda) - R_{\text{sim}}(\lambda, \theta))^2, \quad (1)$$

where  $R_{\text{sim}}$  and  $R_{\text{meas}}$  denote the simulated and measured reflectance in the  $[\lambda_{\min}; \lambda_{\max}]$  spectral range, respectively. In previous work, the LCC of *R. fruticosus* estimated using PROSPECT inversion was consistent with laboratory analyses and strongly linked to TPH concentrations [43]. This method was developed in the field and performed well for predicting the contamination level (i.e., TPH concentration) at leaf scale. In this study, we propose to assess its robustness on field measurements performed at canopy scale and on the airborne images, using the PROSAIL model. PROSAIL results from the coupling of PROSPECT and SAIL models [45]. It expands the scope of PROSPECT to dense canopy reflectance data by taking the influence of canopy architecture, leaf area index (LAI) and bare soil, and illumination and viewing geometry into account [59,60]. The inversion of the model follows the same procedure as that of PROSPECT. In this study, PROSAIL was used for retrieving LCC.

The principle of this method is to quantify TPH from LCC, so we applied it to the contaminated sites. PROSPECT was inverted on leaf reflectance measurements performed on the 10 plots of the brownfield ( $n = 180$ ). On the same plots, PROSAIL was inverted on both field canopy measurements ( $n = 90$ ) and on the pixels from the airborne image ( $n = 184$ ). Inversions were computed using the

differential evolution algorithm [43,61] and the model parameters listed in Table 2. The LCC values retrieved from canopy measurements and from the image were compared to those of leaves using the  $R^2$  and the root mean square error (RMSE) [43].

**Table 2.** Parameter bounds used to compute PROSPECT and PROSAIL (PROSPECT + SAIL) inversions.

Parameter	Unit	Range	Reference
<b>PROSPECT:</b>			
Leaf structure ( $N$ )		1–5	
Chlorophyll a + b ( $C_{ab}$ )	$\mu\text{g}/\text{cm}^{-2}$	1–100	
Carotenoids ( $C_{cx}$ )	$\mu\text{g}/\text{cm}^{-2}$	1–50	[43]
Brown pigments ( $C_{bp}$ )	$\mu\text{g}/\text{cm}^{-2}$	0.01–1	
Water ( $C_w$ )	$\text{g}/\text{cm}^{-2}$	0.001–0.1	
Dry matter ( $C_m$ )	$\text{g}/\text{cm}^{-2}$	0.001–0.1	
<b>SAIL:</b>			
Leaf Area Index (LAI)	$\text{m}^2/\text{m}^{-2}$	0.1–5	
Hotspot ( $hot$ )	$\text{m}/\text{m}^{-1}$	0.01–0.1	
Leaf Inclination Distribution Function (LIDF)		Planophile <sup>1</sup>	[59,60,62–64]
Soil brightness <sup>2</sup> ( $bright$ )		0.5–1.5	
Solar zenith angle ( $\theta_s$ )	deg.	Fixed ( $30^\circ$ )	
Viewing zenith angle ( $\theta_v$ )	deg.	Fixed ( $0^\circ$ )	
Relative azimuth angle ( $\phi_{sv}$ )	deg.	Fixed ( $0^\circ$ )	

<sup>1</sup> As specified for *Rubus fruticosus* L. in [65]. <sup>2</sup> The recent version of PROSAIL includes a simple lambertian soil reflectance model. A brightness parameter ( $bright$ ) was added to account for soil moisture and roughness [59,64].

LCC was then used for quantifying TPH. Each data type (leaf, canopy, and image) was split into 50% training and 50% test sets. Negative exponential models were fitted between LCC and TPH concentrations on the training set and then applied to the test set [43]. TPH predictions were compared to the measured concentrations by computing the  $R^2$ , the RMSE, and the residual predictive deviation (RPD) [66,67]. Since the method was calibrated for TPH concentrations ranging from 17 to 39  $\text{g}/\text{kg}^{-1}$ , it was validated on the mud pit with 24  $\text{g}/\text{kg}^{-1}$  TPH only.

#### 2.4.2. Second Method Based on Elastic Net Regression

The second method of quantification consists of linking the spectral signatures to TPH concentrations directly using multiple regression. Several approaches have been proposed in previous studies aiming to quantify heavy metals from vegetation reflectance in the field, especially partial least square regression (PLSR) [66,68]. PLSR is not suitable for TPH quantification [43], therefore, in this study, we proposed another regression approach, the elastic net (ENET [69]), which shows multiple advantages but remains underexploited in remote sensing of vegetation [70,71]. ENET is a penalized least squared approach that allows efficient variable selection under multicollinearity, which is a major limitation of other multiple regression approaches when dealing with hyperspectral data. Moreover, ENET performed well for tracking alterations in leaf biochemistry induced by oil in a previous study [28].

In the present study, ENET was used for predicting TPH concentration from the spectral signature of vegetation while selecting the most contributing spectral bands. For this purpose, several spectrum transformations were tested which included first and second derivatives, standard normal variate (SNV),  $\text{Log}(1/R)$ , and area under curve normalization (AUCN) (see [34,66,72] for a detailed description of the transformations). All these transformations are likely to enhance the information contained in the spectral signature and to improve TPH predictions. They are illustrated in Figure A1 in the Appendix A. The method was applied to the spectral signatures acquired in the field (at leaf and canopy scales) and on the airborne image, following the same procedure as the PROSAIL method (i.e.,

training and test steps on the brownfield and validation on the other mud pits). The accuracy of TPH predictions were compared between the two methods, as well as their respective advantages.

### 3. Results

#### 3.1. Calibration of the Methods

##### 3.1.1. Detection of Oil Contamination

The RLR-based method exploiting vegetation indices performed well for discriminating between healthy and oil-exposed vegetation from the airborne image. The classification trained on the 10 zones of the brownfield and the large control site reached OA and Kappa of 98% and 0.95 on the test set, respectively. Only little confusions were made between healthy and oil-exposed vegetation (Table 3). Within the brownfield, the misclassified pixels came from the least contaminated plots (17–18 g/kg<sup>-1</sup>). Almost all pixels from the large control site were correctly classified. These results were consistent with those of previous studies carried out under controlled and field conditions on the same species, at leaf and canopy scales [28,34].

**Table 3.** Confusion matrix obtained from the regularized logistic regression (RLR) classification on the test set using the 14 vegetation indices. The brownfield class denotes the pixels from the 10 zones of the brownfield, and the control denotes those from the large control site.

	Brownfield	Control	User's Accuracy (%)
Brownfield	88	4	95,7
Control	2	192	99.0
Producer's accuracy (%)	97.8	98.0	

The robustness of the method to upscaling (i.e., at leaf and canopy scales and imagery) is due to the limited influence of plant architecture, bare soil, and illuminating and viewing geometry on the selected vegetation indices at high spatial resolution. These factors usually affect the ability of vegetation indices to detect changes in leaf biochemistry from canopy measurements or optical images [73–75]. This phenomenon was likely to induce confusion between healthy and oil-exposed vegetation, however, the 14 indices used in the method have been specifically selected for their robustness to upscaling and their link with oil-induced effects on leaf biochemistry [76–78]. These indices mainly depend on chlorophylls a and b,  $\beta$ -carotene, and lutein contents for bramble [28] (see Table A1 in the Appendix A). They are weakly affected by the abovementioned factors (especially bare soil). Therefore, they allow tracking alterations in leaf pigment contents specifically induced by oil with good accuracy, regardless of the acquisition scale [28].

##### 3.1.2. Quantification of Soil TPH Content

###### PROSAIL-Based Method

LCC estimated from the inversions of PROSPECT and PROSAIL models on the 10 plots of the brownfield is presented in Figure 2. LCC estimations were strongly consistent among data types (i.e., leaf, canopy, and airborne image), especially in the field ( $R^2 = 0.95$  and  $RMSE = 1.05 \mu\text{g}/\text{cm}^{-2}$ , Figure 2a) and ranged from 53 to 69  $\mu\text{g}/\text{cm}^{-2}$ , which is particularly high for vegetation exposed to contamination. This highlights the tolerance of bramble to oil exposure and explains its establishment on industrial sites under temperate regions [36,43,79,80]. PROSAIL is a one-layer model adapted to dense vegetation. Its application to the airborne image succeeded in retrieving LCC, thanks to very high spatial resolution. As expected, estimations were slightly less accurate and showed a higher variability within the plots than for field measurements ( $R^2 = 0.85$ ,  $RMSE = 3.70 \mu\text{g}/\text{cm}^{-2}$ , Figure 2b).

**Figure 2.** (a–b) Leaf chlorophyll content (LCC) (mean  $\pm$  SD) retrieved from PROSPECT and PROSAIL model inversions on the 10 plots of the brownfield. (a) Comparison between leaf and canopy measurements from the field and (b) between leaf measurements and the airborne image.

LCC exhibited a close negative relationship with soil TPH content on the training set ( $0.74 < R^2 < 0.87$ , Figure 3a–c). The more the soil was contaminated, the more LCC decreased. This relationship has been previously noticed under controlled conditions for oil-sensitive species and has been linked to the reduction of water and nutrient availability in soil and the alteration of root uptake capacities [23,81,82]. Similar observations have been made under natural conditions on bramble at leaf scale [43]. However, our method is the first to bring evidence of this relationship at leaf and canopy scales and on airborne images. Its application to the test set resulted in accurate predictions of TPH concentrations (Figure 3d–f). Results were very close at leaf and canopy scales (RMSE = 2.62 and 2.85  $\text{g}\cdot\text{kg}^{-1}$  and RPD = 2.26 and 2.15, respectively), thanks to consistent LCC described above (Figure 2a). A higher variability in LCC was observed on the image and led to a lower accuracy in TPH predictions (RMSE = 3.2  $\text{g}\cdot\text{kg}^{-1}$  and RPD = 2), in comparison to field measurements. The highest level of contamination (39  $\text{g}\cdot\text{kg}^{-1}$ ) was more difficult to predict and contributed considerably to inaccuracies. As previously observed at leaf scale, TPH are particularly difficult to quantify above a certain concentration [43], probably because variations in LCC become too subtle to be caught from imagery. In contrast, LCC rapidly shifts for moderate levels of contamination (20–30  $\text{g}\cdot\text{kg}^{-1}$ ) and makes predictions more accurate.

**Figure 3.** (a–c) Relationship between LCC and soil total petroleum hydrocarbons (TPH) content observed on the training set on the 10 plots of the brownfield, at (a) leaf and (b) canopy scales and (c) on the airborne image. (d–f) Comparison between measured and predicted TPH concentrations on the test set, at (d) leaf and (e) canopy scales and (f) on the airborne image.

### Elastic Net Based Method

The ENET regression based on the original and transformed spectral signatures also succeeded in predicting TPH concentrations on the brownfield (Figure 4). However, the overall performance of the method was lower than that based on PROSPECT and PROSAIL inversions, regardless of the transformation. Although TPH predictions were good for the original-reflectance-spectra for all scales (RMSE  $\leq 4.04$  g/kg<sup>-1</sup>), they were improved using first and second derivatives (RMSE  $\leq 3.53$  g/kg<sup>-1</sup>), mainly due to better quantification of the highest level of contamination (39 g/kg<sup>-1</sup>) at canopy scale and on the airborne image. Conversely, predictions were almost unchanged with the Log(1/R) transformation and less accurate using SNV and AUCN ones. As for the PROSPECT and PROSAIL based method, the accuracy of predictions was reduced while increasing acquisition scale (best RPD = 2.16, 2.07 and 1.9 at leaf and canopy scales and on the image, respectively, Figure 4).

**Figure 4.** Comparison between measured and predicted TPH concentrations on the test set on the 10 plots of the brownfield using the elastic net regression on the original and transformed spectral signatures (in columns). First, second, and third rows show the results obtained at leaf and canopy scales and on the airborne image, respectively.

Spectrum transformations have been extensively used for detecting vegetation stress in various contexts, including oil contamination [30,34,83,84]. The first derivative sparked particular interest, as it allows tracking shifts in the red edge position (REP) caused by chlorophyll alteration [20,29,85]. Therefore, the REP has been many times depicted as a reliable indicator of alterations in vegetation health following exposure to TPH [86], however, many other environmental stressors also affect the REP [22,83], which might lead to inaccuracies in TPH quantification. In our case, the ENET method highlighted the importance of the red edge, and to a greater extent the VIS region, for quantifying TPH, since most contributing bands were concentrated around 550 and 700 nm. This trend remained consistent among data types (leaf, canopy, and image) and between reflectance and derivative spectra (Figure 5), and therefore confirmed the involvement of chlorophylls in the response of vegetation to oil. The red edge was almost sufficient alone for predicting TPH using first derivative spectra, especially at leaf and canopy scales. Additional spectral bands from the SWIR region were often selected on the airborne image. These bands have been linked to leaf water, cellulose, and lignin contents in previous studies [87,88], but remained of less contribution to TPH predictions in our case. In contrast, SNV, Log(1/R), and AUCN transformation degraded TPH predictions, and did not provide a clear interpretation of the contributing spectral bands (Figure 5). These transformations are usually employed for reducing the high variability of spectral signatures while enhancing the information they

contain [34,66]. In our case, reflectance varied little along the gradient of TPH ( $\leq 10\%$  at 550 nm and in the red edge), because of the strong tolerance of bramble to oil exposure, in comparison to other species [20,30]. SNV, Log(1/R), and AUCN transformations were unable to conserve this information in the transformed spectra, which introduced inaccuracies in TPH predictions.

**Figure 5.** Coefficients obtained by the elastic net (ENET) method on the 10 plots of the brownfield using the original and transformed spectral signatures (in columns). First, second, and third rows show the results obtained at leaf and canopy scales and on the airborne image, respectively. The spectral bands contributing to TPH predictions are denoted by nonzero coefficients.

### 3.2. Validation of the Methods

#### 3.2.1. Validation of Oil Detection

When applied to the validation sites, the method of oil detection based on the vegetation indices succeeded in detecting healthy vegetation. The ecological differences among the sites (soil properties and surrounding ecosystem) were challenging, because they could introduce variability in reflectance, and thus in index values, however, this had only a little influence on the performance of the method, since more than 91% of the pixels from the five control sites used for validation were correctly labelled (OA = 91.8%, Table 4). Conversely, the level of oil contamination was critical for the detection of mud pits. Accuracy averaged 50.5% on the four validation mud pits and resulted from strong differences among sites. As expected, the most contaminated one ( $24 \text{ g/kg}^{-1}$ ) was well classified (95.5%), as it was in the range of the method calibration ( $17\text{--}39 \text{ g/kg}^{-1}$ ). Conversely, accuracy rapidly fell for the other mud pits, where low TPH concentrations were observed. More precisely, the two least contaminated sites ( $0.25$  and  $0.38 \text{ g/kg}^{-1}$  TPH) were poorly classified (accuracy of 6.1% and 15%, respectively, Table 4), because vegetation indices from these sites exhibited values similar to that of the control ones. These results emphasize the limits of the method. Below a certain concentration, oil no longer alters leaf pigment and water contents, so soil contamination becomes very difficult to detect using vegetation reflectance [21,28,30]. This detection limit strongly depends on the sensitivity of the species, and is higher for oil-tolerant species [20,33,38,89]. Thus, the closer the level of contamination to this limit, the less accurate the classification. In our case, this level was probably below the detection limit for bramble in the two least contaminated sites. Conversely, the method performed well for detecting the fourth validation mud pit contaminated by  $3.15 \text{ g/kg}^{-1}$  TPH. More than 85% of pixels from this site were correctly labelled, despite its contamination level being outside the calibration range. Hence, oil still induces important effects on leaf biochemistry of bramble at moderate contamination levels, which can be detected using the proposed method.

**Table 4.** Confusion matrix obtained from the RLR classification on the validation sites using the 14 vegetation indices.

	C <sub>10</sub> -C <sub>40</sub> TPH (g/kg <sup>-1</sup> )	Mud Pit	Control	User's Accuracy (%)
Control <sup>1</sup>	<DL	13	146	91.8
Mud pit	0.25	2	31	6.1
	0.38	3	17	15
	3.15	41	7	85.4
	24	21	1	95.5

<sup>1</sup> The five control sites were grouped for more concision.

### 3.2.2. Validation of TPH Quantification

The two methods of quantification were applied to the mud pit contaminated by 24 g/kg<sup>-1</sup> TPH and confirmed their potential for application to airborne hyperspectral images. The TPH concentrations were estimated to 23.69 ( $\pm$  1.93) and 23.39 ( $\pm$  2.41) g/kg<sup>-1</sup> using PROSAIL inversions and ENET with first derivative spectra, respectively. Predictions were slightly less accurate using other spectrum transformations (SNV, Log(1/R), and AUCN), but remained very close to the measured level of contamination (data not shown). Both methods, thus, provide reliable quantification of TPH in the context of our study. It is, however, important to note that the concentration observed on this mud pit corresponded to that for which best predictions were obtained on the brownfield (Figures 3 and 4). This explains the high accuracy of predictions observed here. Unfortunately, none of the four validation mud pits exhibited TPH concentrations above 35 g/kg<sup>-1</sup> which was probably the most difficult to predict. It was thus not possible to validate the methods for such concentrations, but an underestimation would be probably observed, as on the brownfield. More generally, some inaccuracies in both methods of quantification might result from local variations in soil TPH content. These local variations introduce variability in bramble reflectance and might have affected TPH predictions, as suspected at leaf scale in previous study [43].

## 4. Discussion and Perspectives

To date, there was no remote sensing method for both detecting and quantifying oil contamination in vegetated areas based on hyperspectral imagery [19,31,32]. Our study is the first to achieve it using very high spatial resolution images acquired in a temperate region. This opens up encouraging perspectives for application of the methods over oil industrial facilities. In a perspective of operational use, it is essential that remote sensing provides reliable detection and quantification of oil over large vegetated areas. Until now, the proposed methods remained poorly effective outside the calibration site [19,32,90], making them unusable operationally. Conversely, those developed in this study were successfully validated, by detecting and quantifying oil on independent mud pits that did not serve for method calibration. Our methods were, however, applied under several assumptions. Since we focused on *R. fruticosus* in the temperate context, the methods were only adapted to this species. Thus, they could be applied for identifying new contaminated mud pits and for quantifying TPH, provided the sites are colonized by dense *R. fruticosus* covers with known location. This is of great interest for monitoring contamination, because this species is widespread on industrial sites under temperate regions [36,79,91]. In an operational perspective, the methods should be applicable at a large scale (i.e., to entire images) in a wide range of contexts (in terms of species, contamination type and level, and environmental conditions). No extensive computational time was noticed in this study, but this should be considered when applying our methods to entire images. Thanks to a good revisit time and large spatial coverage [22], satellite-embedded sensors show great interest for monitoring oil contamination continuously over industrial facilities, however, our methods were tested on a single date, so they should be first validated over a longer time scale [22,43]. In addition, to date, none of the operating and planned hyperspectral satellite-embedded sensors covering the reflective domain offer a spatial resolution higher than 8 m with more than 250 spectral bands. It is highly probable that, when

applying our methods to satellite imagery, changes in spatial and spectral resolutions will affect their performance. Thus, in order to support oil exploration and contamination monitoring, the methods should improve in two ways. First, by extending their scope, and then, by adapting them to satellite imagery. These two perspectives are discussed jointly in this section.

At this stage, the need to know the location of *R. fruticosus* is one of the most important limits to the application of the methods at a large scale. The mapping of *R. fruticosus* could be achieved quite easily for homogenous and dense covers, such as those studied here. Conversely, *R. fruticosus* is more likely to be mixed with other species and bare soil in pixels using satellite imagery, affecting the values of the 14 VI used in the detection method and consequently reducing its accuracy. Likewise, PROSAIL inversions might experience difficulties in retrieving LCC accurately for sparse or plurispecific vegetation, because of the influence of bare soil and differences in optical properties, leaf orientation, and sensitivity to oil among species [45,62]. In response to this limit, spectral unmixing [92–95] seems a promising solution. It could be used for mapping *R. fruticosus*, even mixed with bare soil or other species, before applying our methods of oil detection and quantification. A successful mapping of *R. fruticosus* has been achieved using unmixing methods on HyMap images (spatial resolution < 10 m) in a previous study [95]. Future studies should focus on assessing unmixing methods on known sites with this species, for example by degrading 1 m spatial resolution airborne images to 8 m and 30 m resolution. In that sense, it might be interesting not to limit to a single species in our case. This would be spatially too restrictive from an operational point of view, so an important effort remains to adapt our methods to other species. Other temperate species might serve for detecting and quantifying oil, such as *Q. pubescens* and *P. canadensis*, as highlighted in our previous study [43]. Thus, they could be used along with *R. fruticosus* for assessing mud pit contamination at a large scale, after being identified by spectral unmixing.

Even if the methods can be applied to entire images, provided that the target species have been identified, it is important to note that their performance depends on the level of contamination. With respect to *R. fruticosus*, the method of detection was initially adapted to a high TPH concentration ( $\geq 17 \text{ g/kg}^{-1}$ ). Satisfying accuracy was obtained for low-contaminated mud pit ( $3.15 \text{ g/kg}^{-1}$  TPH), but accuracy fell below  $1 \text{ g/kg}^{-1}$  TPH. This helped determining a lower detection limit. Conversely, the method of quantification based on LCC retrieval was accurate within the range of TPH studied. Its exact range of effectiveness remains, however, unknown. Thus, further research should focus on determining the exact limits of detection and quantification of the methods. These limits may vary among species, depending on their sensitivity. All of them do not allow detecting and quantifying mud pit contamination in the same range. Species with different sensitivities could be complementary for quantifying TPH over a wide range of concentrations. Spatial resolution might be also crucial, especially if TPH concentrations vary locally. In the case of 8 m or 30 m satellite imagery, pixels may include vegetation exposed to varying levels of contamination, making it difficult to quantify accurately. An important effort still remains to determine which species are suitable for applying the methods and their respective range of effectiveness at different spatial resolutions.

Although the scope of the methods is restricted to assessing mud pit contamination (i.e., production residues and oil sludge) at this stage, it should extend to other scenarios. Crude oil or petroleum product leaks deriving from pipeline or storage tank failures are a priority. Along with wastewater, they represent the main sources of contaminant release from oil industry [6,96]. Moreover, the detection of crude oil is of great interest in microseepage prospecting. This represents a major way of improvements toward operational applications. From the perspective of operational application, one possible limit to applying our methods may arise at the spatial resolution of satellite images for punctual oil patches. Microseepage and mud pits generally occupy large areas ( $>30 \text{ m}$ ), but pipeline and storage tank leaks can occur on a few square meters [17,97]. Their detection might be very difficult without very high spatial resolution, because pixels will rarely include only oil-exposed vegetation. Thus, it is important to keep in mind that the needed spatial resolution also depends on the purpose of the detection and quantification of oil.

## 5. Conclusions

This study aimed to detect and quantify oil contamination (i.e., TPH) in soils in temperate vegetated areas using airborne imagery with very high spatial and spectral resolutions. A two-step approach was proposed. As a first step, a method of detection exploiting 14 vegetation indices performed well for discriminating between healthy and oil-exposed bramble plants (OA = 98% and kappa = 0.95). This method was tested on additional sites and succeeded in detecting oil contamination levels similar to those of the calibration site (17–39 g/kg<sup>-1</sup>). Then, the performance of the method decreased for lower levels of contaminations, especially below 1 g/kg<sup>-1</sup>. As a second step, two methods of TPH quantification were proposed and assessed on the same contaminated sites. The first one, which relied on LCC retrieval using PROSPECT and PROSAIL models, achieved accurate predictions of TPH concentrations both in the field, at leaf and canopy scales, and on the airborne image (RMSE ≤ 3.20 g/kg<sup>-1</sup> and RPD ≥ 2), thanks to consistent LCC estimations. The second method combined spectrum transformations with ENET regression. This method provided slightly less accurate quantification of TPH (best RMSE ≤ 3.28 g/kg<sup>-1</sup> and RPD ≥ 1.9) and required only few spectral bands in the VIS and the red edge regions. Both methods were validated on another contaminated site and their performances were compared.

In the continuity of previous work, this multiscale study highlighted the importance of controlled and field conditions for developing reliable methods that can be applied to hyperspectral imagery. Our methods focused on tracking oil-induced alterations in leaf biochemistry while preventing from undesired effects (plant architecture, bare soil, and illuminating and viewing geometry), which made them accurate regardless of the acquisition scale. High spatial resolution helped achieving this. As discussed above, further studies are needed to adapt our methods to various ecological contexts subject to oil contamination. In addition, promising perspectives of operational use will arise in the future with the emergence of new hyperspectral satellite sensors.

## Appendix A

**Table A1.** Vegetation indices used in the method of detection. For each index, the related biochemical parameters are specified. These parameters have been identified in a previous study carried out on *R. fruticosus*, under controlled conditions [28]. (Chl, total chlorophylls; Lut, lutein; B-car, β-carotene; Ant, antheraxanthin; Zea, zeaxanthin; Vio, violaxanthin; and LWC, leaf water content).

Index	Formula	Reference	Related Parameter
Chlorophyll/Carotenoids Index	$CCI = D_{720}/D_{700}$	[98]	Chl, B-car
Carter Index 2	$CTR2 = R_{695}/R_{760}$	[99]	Chl, Lut
Gitelson & Merzlyak Index 1	$GM1 = R_{750}/R_{550}$	[77]	Chl, B-car
Gitelson & Merzlyak Index 2	$GM2 = R_{750}/R_{700}$	[77]	Chl, B-car
modified Simple Ratio 705 nm	$mSR705 = (R_{750} - R_{445})/(R_{750} + R_{445})$	[26]	Chl, B-car
MERIS Terrestrial Chlorophyll Index	$MTCI = (R_{754} - R_{709})/(R_{709} + R_{681})$	[76]	Chl, B-car
Normalized Difference 705 nm	$ND705 \text{ or } NDVI705 = (R_{750} - R_{705})/(R_{750} + R_{705})$	[26]	Chl, B-car
Photochemical Reflectance Index 2	$PRI2 = (R_{531} - R_{570})/(R_{531} + R_{570})$	[100]	Chl, B-car
Photochemical Reflectance Index 3	$PRI3 = (R_{570} - R_{539})/(R_{570} + R_{539})$	[100]	Lut, B-car

Table A1. Cont.

Index	Formula	Reference	Related Farameter
Structure Intensive Pigment Index 2	$SIPI2 = (R_{800} - R_{505}) / (R_{800} + R_{690})$	[73]	Lut, Ant
Simple Ratio 705 nm	$SR705 = R_{750} / R_{705}$	[26]	Chl, B-car
Vogelmann Index 2	$VOG2 = (R_{734} - R_{747}) / (R_{715} + R_{726})$	[78]	Lut
Vogelmann Index 3	$VOG3 = (R_{734} - R_{747}) / (R_{715} + R_{720})$	[78]	Lut
Disease Water Stress Index	$DWSI = (R_{800} - R_{550}) / (R_{1660} + R_{680})$	[101]	LWC

Figure A1. Original and transformed spectral signatures acquired in the brownfield at leaf and canopy scales and from the airborne image. The bold curve represents the median spectral signature and the colored area represents the (min:max) interval.

Figure A2. Flowchart of the approach proposed in this study. The method of oil detection was developed and tested at leaf and canopy scales in [28], so it was only evaluated on the airborne image in this study. The two methods of total petroleum hydrocarbons (TPH) quantification were tested in the field at leaf and canopy scales and on the airborne image. All the methods were first calibrated on study sites and validated on additional sites (see Table 1 for details about the sites).
