- **Abstract:** Spatial prediction of soil ammonia (NH<sup>3</sup> ) plays an important role in monitoring climate warming and soil ecological health. However, traditional machine learning (ML) models do not consider optimal parameter selection and spatial autocorrelation. Here, we present an integration method (tree-structured Parzen estimator–machine learning–ordinary kriging (TPE–ML–OK)) to predict spatial variability of soil NH<sup>3</sup> from Sentinel-2 remote sensing image and air quality data. In TPE–ML–OK, we designed the TPE search algorithm, which encourages gradient boosting decision tree (GBDT), random forest (RF), and extreme gradient boosting (XGB) models to pay more attention to the optimal hyperparameters' high-possibility range, and then the residual ordinary kriging model is used to further improve the prediction accuracy of soil  $NH<sub>3</sub>$  flux. We found a weak linear correlation between soil NH<sup>3</sup> flux and environmental variables using scatter matrix correlation analysis. The optimal hyperparameters from the TPE search algorithm existed in the densest iteration region, and the TPE–XGB–OK method exhibited the highest predicted accuracy ( $R^2 = 85.97\%$ ) for soil NH<sub>3</sub> flux in comparison with other models. The spatial mapping results based on TPE–ML–OK methods showed that the high fluxes of soil  $NH<sub>3</sub>$  were concentrated in the central and northeast areas, which may be influenced by rivers or soil water. The analysis result of the SHapley additive explanation (SHAP) algorithm found that the variables with the highest contribution to soil NH<sub>3</sub> were O<sub>3</sub>, SO<sub>2</sub>, PM<sub>10</sub>, CO, and NDWI. The above results demonstrate the powerful linear–nonlinear interpretation ability between soil NH<sub>3</sub> and environmental variables using the integration method, which can reduce the impact on agricultural nitrogen deposition and regional air quality.

**Keywords:** soil ammonia; XGBoost; ordinary kriging; spatial prediction; hyperparameter

## **1. Introduction**

As an alkaline gas, ammonia ( $NH<sub>3</sub>$ ) can effectively reduce the occurrence of acid rain  $[1,2]$  $[1,2]$ . NH<sub>3</sub> can be used to synthesize fertilizers, which greatly improves agricultural productivity and meets growing food demand [\[3\]](#page-17-2). However, the large-scale volatilization of NH<sub>3</sub> into the atmosphere leads to air pollution and nitrogen deposition, which leads to the eutrophication of water bodies and the destruction of biodiversity  $[4,5]$  $[4,5]$ . As an indirect source of nitrogen dioxide  $(N_2O)$  emissions, NH<sub>3</sub> has an important impact on global warming. It is estimated that the potential of carbon dioxide  $(CO<sub>2</sub>)$  to cause global warming is only about 1/265 times that of N<sub>2</sub>O in one hundred years [\[6,](#page-17-5)[7\]](#page-17-6), and global NH<sub>3</sub> emission is projected to increase rapidly to 132 Tg by 2100 [\[8\]](#page-17-7), with the major emission

source of  $NH<sub>3</sub>$  being agriculture. The nitrification of  $NH<sub>3</sub>$  will lead to soil acidification and eutrophication [\[9\]](#page-17-8).  $NH_3$  is highly dependent on environmental variables compared to other gases due to its volatile characteristics [\[9](#page-17-8)[–11\]](#page-17-9). Therefore, there is an urgent need for rapid and effective methods to predict NH<sup>3</sup> emissions from the soil with environmental variables to provide data support for alleviating NH<sup>3</sup> emissions or studying NH<sup>3</sup> from soil-influencing factors.

Traditional soil NH<sup>3</sup> measurement requires a lot of sampling work, which consumes significant manpower resources and causes cost waste. Additionally, laboratory determination requires using a concentrated sulfuric acid  $(H_2SO_4)$  and boric acid  $(H_3BO_3)$  solution. The time period for obtaining soil  $NH<sub>3</sub>$  content is long, and it can easily cause secondary environmental pollution. Spatial prediction is an important method that can be used to realize the continuous distribution of  $NH<sub>3</sub>$  in farmland soil in comparison with the high cost and difficulty of a soil NH<sup>3</sup> content survey. It is essential to develop a high-performance prediction model with efficient environment variables for spatial prediction of soil  $NH<sub>3</sub>$  flux, which is of profound significance to alleviating global warming and improving air quality.

Air quality (such as  $PM<sub>2.5</sub>$ , NO<sub>2</sub>, and SO<sub>2</sub>) has been shown to closely interact with soil ammonia. Because of the important role of  $NH<sub>3</sub>$  in aerosol nucleation and haze [\[12\]](#page-17-10), the gradual decrease in the formation of  $NH<sub>4</sub><sup>+</sup>$  aerosols will lead to a significant increase in the residence time of  $NH<sub>3</sub>$  in the atmosphere [\[13\]](#page-17-11), while excessive  $NH<sub>3</sub>$  stays in the aerosol phase, which may reduce the removal of the condensed phase [\[14\]](#page-17-12). On the contrary, the reaction of SO<sub>2</sub> and NH<sub>3</sub> with active radicals and NO<sub>x</sub> may also affect the formation of O<sub>3</sub> and secondary aerosol intermediates [\[15,](#page-17-13)[16\]](#page-17-14). Gu et al. (2022) found that the reduction in acidic precursors sulfur dioxide and nitrogen oxides in recent years has also reduced the chemical sink of  $NH_3$  in the atmosphere [\[13\]](#page-17-11). This is because gaseous  $NO_2$  is a reaction intermediate that reacts with  $NH_3$ ;  $NH_3$  has a good adsorption effect on  $NO_2$ . The concentration of  $SO_2$ ,  $NO_2$ ,  $CO$ , and other precursors is significantly higher, which may impact the production of  $NH_4^+$  in the environment [\[14\]](#page-17-12).

A large number of methods have been widely used in the field of soil gas flux prediction. Geostatistical interpolation is a basic method that can estimate the target of any coordinate with zero deflection and minimum variance [\[17,](#page-17-15)[18\]](#page-18-0). For example, Roberto et al. collected 50 soil  $CO<sub>2</sub>$  flux samples using the dynamic concentration method and interpolated the discrete points to obtain the spatial variability result of  $CO<sub>2</sub>$  flux in the survey area based on the ordinary kriging (OK) model [\[19\]](#page-18-1). However, since only the spatial coordinates have no information about other auxiliary variables, the semivariogram constructed by the kriging method depends on the measured point pairs, resulting in low spatial prediction accuracy of soil gas flux [\[20\]](#page-18-2).

With the development of artificial intelligence, the machine learning (ML) method is often used to construct the relationship between environmental variables and targets, and is applied extensively in the prediction of farmland soil gas flux [\[20](#page-18-2)[,21\]](#page-18-3). The commonly used models include support vector machine (SVM), artificial neural network (ANN), random forest (RF), and gradient-boosted regression (GBR). For example, Abbasi et al. used the RF model with multi-source input variables (i.e., air temperature, soil organic matter, soil moisture, soil total carbon, solar radiation, etc.) to predict  $CO<sub>2</sub>$  fluxes from the soil in the inorganic fertilizer environment in combination with field measured  $CO<sub>2</sub>$  fluxes [\[22\]](#page-18-4). Morad et al. used the RF model, multivariate adaptive spline curve (MDSC), and general linear model (GLM) to predict soil  $NO, CO<sub>2</sub>$ , and nitrogen oxide fluxes under no-tillage and conventional tillage, respectively, in the case of temperature, soil moisture, and crop straw rate as environmental variables and found that the prediction results of RF model were the best [\[21\]](#page-18-3). Daniel et al., used quantile regression forests to predict the distribution of soil–atmosphere  $CH_4$  and  $CO_2$  fluxes in forest watersheds in different seasons by inputting DEM-derived topographic attributes [\[23\]](#page-18-5). The ML method is an efficient and robust substitution compared with traditional soil gas measurement methods [\[22](#page-18-4)[,24\]](#page-18-6).

However, the existing ML models suffer from two shortcomings in explaining the relationship between environmental variables and soil gases. On the one hand, the prediction

performance of ML models is affected by hyperparameters. Previous studies have shown that hyperparameters can significantly affect the performance and accuracy of prediction models. Additionally, these hyperparameters also affect each other. It is difficult to capture the global optimal hyperparameters of the prediction model by using artificial trial-anderror experimentation and default hyperparameters. The automatic parameter adjustment method with high efficiency and robustness is an important auxiliary method to realize automatic ML [\[19\]](#page-18-1). For example, Yan et al., used a grid search (GS) algorithm to optimize and find the hyperparameters of the RF model, light gradient boosting machine (LGBM), and adaptive boosting models to adjust the parameter values so that the model performed best [\[25\]](#page-18-7). However, the GS algorithm is very time-consuming because it traverses all parameters in an isolated manner [\[26\]](#page-18-8) and cannot meet the requirements of identifying global optimality [\[27\]](#page-18-9). Zhu et al., used an efficient Bayesian optimization method to find the optimal combination of hyperparameters of the extreme gradient boosting (XGB) model with higher prediction accuracy than GS [\[26\]](#page-18-8). On the other hand, the interpretation of the relationship between environmental variables and soil gas by ML is monotonous. The ML model has certain limitations on the data set and is suitable for nonlinear data sets [\[21\]](#page-18-3), ignoring the spatial autocorrelation between adjacent observation data [\[28\]](#page-18-10).

A new prediction model, the integration kriging model, has been proven to be more accurate in predicting soil properties in many current studies [\[29](#page-18-11)[–35\]](#page-18-12). For example, Guo et al. found that the integration method has advantages in predicting the spatial variability of soil organic matter in the case of comparing the methods of RF, stepwise linear regression (SLR), and the combination of RF and residual kriging by inputting topographic attributes, such as geological units, climate factors, and vegetation indices [\[28\]](#page-18-10). Based on 73 years of  $NO<sub>2</sub>$ observation data from 14 monitoring stations, Chen et al. predicted the spatial–temporal characteristics of  $NO<sub>2</sub>$  concentrations in Taiwan using the  $NO<sub>2</sub>$  data interpolated kriging method and the land use regression model with local non-traditional geographical predictors [\[36\]](#page-18-13).

However, whether the integration of the TPE-based ML model and geostatistical model can significantly improve the spatial prediction accuracy and explain the relationship between environmental variables and soil NH<sub>3</sub> flux is still unclear (i.e., nonlinear and linear coupling characteristics). Therefore, to overcome the limitations of the hyperparameter adjustment and spatial autocorrelation neglect of ML modeling, the objective of this study is to demonstrate the increased predicted model performance using TPE–ML–OK-based models with Sentinel-2 remote sensing image and air quality data, which involves establishing ML models, determining the optimal hyperparameters using the TPE algorithm, building a residual ordinary kriging model, and revealing the relationships between key variables and soil  $NH<sub>3</sub>$  flux via explainable analysis. The environment variables (i.e., Sentinel-2 remote sensing image and air quality data) related to soil  $NH<sub>3</sub>$  were collected first. Then, the tree-structured Parzen estimator (TPE) search was applied to find the optimal hyperparameters of the gradient boosting decision tree (GBDT), random forest (RF), and extreme gradient boosting (XGB) models, and the residual ordinary kriging model was used to further predict and mapping the soil  $NH<sub>3</sub>$  flux. Finally, the relationships between environmental variables and soil  $NH<sub>3</sub>$  were evaluated using the SHapley additive explanation (SHAP) method.

#### **2. Materials and Methods**

Figure [1](#page-3-0) shows the flowchart in this study and includes three phases: (i) collection and preprocessing of sampling and environmental variable data (vegetation index and texture features from Sentinel-2 L2A image, interpolation analysis of air quality stations data, and soil NH<sup>3</sup> sampling); (ii) construction of integration method (machine learning model, TPE hyperparameter optimization, and residual ordinary kriging); and (iii) accuracy evaluation of prediction results, soil mapping using TPE–ML–OK models, and importance analysis of environmental variable using the SHAP method.

### 2.1. Overview of Study Area *2.1. Overview of Study Area*

The study area is situated in the Yellow River Delta (YRD), East China (36°55'-38°10'N,  $118°07'$ – $119°10'E$ ). It has a temperate continental monsoon climate, and the terrain inclines from southwest to northeast along the Yellow River (Figure [2\)](#page-4-0). Soil types are divided into five categories: cinnamon soil, Shajiang black soil, fluvo-aquic soil, saline soil, and paddy soil. Based on the statistical yearbook of Dongying in 2020, the average temperature in the study area is 14.1 °C, the annual precipitation is 665.3 mm, and the annual sunshine hours are 2998.5 h. The study area mainly contains oil, natural gas, oil shale, and many other mineral resources, which is the main production area of the Shengli Oilfield. However, the soil pollution caused by oilfield development in this area indirectly affects the survival rate of soil microorganisms and, thus, the absorption, transformation, and utilization of NH<sub>3</sub> by some soil microorganisms, which changes the NH<sub>3</sub> content in the soil. Spatial prediction of soil NH<sub>3</sub> is of great significance in improving microclimate change, air pollution, and nitrogen loss from farmland in the study area.

#### *2.2. Soil Sample Collection and Analysis*

In the farmlands of the study area, 134 sampling points were uniformly and randomly arranged from 22 September 2022 to 29 September 2022. The  $NH<sub>3</sub>$  volatilization was measured per day at 8:00–10:00 a.m. and 3:00–5:00 p.m. The concentration of NH<sub>3</sub> was determined using the continuous airflow enclosure method, and a cylindrical plexiglass chamber (20 cm in diameter and 30 cm in height) was installed in the soil of each sample plot. We inserted the air chamber into the soil of 5 cm and connected the air in the glass chamber from the air outlet to the pump-suction gas-phase speedometer (FZ2800-2, Guangzhou, China) through the pipeline. The measurement interval of each sample point was 10 min, the measurement was carried out in three parallels, and the initial and final  $NH<sub>3</sub>$  content (unit ppm) was recorded on the spot. The initial  $NH<sub>3</sub>$  content was converted into emission flux (unit: kg N ha<sup>-1</sup> d<sup>-1</sup>) according to Equation (1) [\[37,](#page-18-14)[38\]](#page-18-15).

$$
AE = c \times v \times 14 \times 1440 \times 10^6 \times 10^{-9} / (mv \times 0.0177)
$$
 (1)

*AE* represents the volatilization flux of NH<sup>3</sup> in farmland soil, *c* represents the content of soil NH<sub>3</sub> (m mol mol<sup>-1</sup>) from the pump-suction gas-phase speedometer, *v* represents the air velocity (0.25 L min $^{-1}$ ), 14 represents the molar mass of NH<sub>3</sub> (g mol $^{-1}$ ), 1440 represents the conversion from min<sup>-1</sup> to d<sup>-1</sup> (1 d 1440 min), 10<sup>6</sup> represents the conversion from m<sup>-2</sup>

<span id="page-4-0"></span>

to ha<sup> $-1$ </sup>, 10<sup> $-9$ </sup> represents the conversion from mg N into kg N, *mv* represents the molar volume of the NH<sub>3</sub>, and 0.0177 is the covered area of the air chamber  $(m^2)$ .

Figure 2. The study area location and sampling points of NH<sub>3</sub> in farmland soil.

# 2.2. Soil Sample Collection and Analysis *2.3. Environmental Variables*

# 2.3.1. Remote Sensing Data

Based on the Sentinel-2 L2A remote sensing image (23 September 2022), the remote sensing index was calculated and obtained. The data comes from the European Space Agency [\(https://scihub.copernicus.eu/,](https://scihub.copernicus.eu/) accessed on 12 November 2022). The L2A image data were preprocessed (i.e., atmospheric correction), and four vegetation index factors were calculated using band 2, band 3, band 4, band 5, band 6, and band 8, including visible atmospheric resistant index (VARI), soil-adjusted vegetation index (SAVI<sub>red</sub>), normalized difference water index (NDWI), and plant senescence reflectance index (PSRI) (Table [1\)](#page-4-1); the resolution of all vegetation variables was  $10~\text{m} \times 10~\text{m}$ .

<span id="page-4-1"></span>**Table 1.** Indexes derived from Sentinel-2 L2A image.

Texture features can reflect additional information, such as hue changes and attributes of remote sensing images, and have been widely used in the extraction or classification of ground object information [\[43](#page-18-20)[–45\]](#page-18-21). For example, many studies have used the GLCM method to calculate the relative frequency between the pixel brightness values of remote sensing images to obtain spatial information gain, which effectively improves the interpretation and classification accuracy of ground objects [\[46–](#page-18-22)[48\]](#page-19-0). Based on the 11 bands of the preprocessed Sentinel-2 L2A image, the texture features were also calculated and analyzed using filter/co-occurrence measures in ENVI 5.3 software. A total of 88 texture features were obtained, including eight transformations: entropy (ENT), correlation (CORR), mean (MEAN), homogeneity (HOM), contrast (CTRA), dissimilarity (DIS), angular second moment (SECM), and variance (VAR). In order to simplify the variable dimension, the first three principal components were obtained using principal component analysis (PCA) in ENVI 5.3 software, and the total variance contribution rate that can be explained is 65.83%. The features with high load values of PC1, PC2, and PC3 were mainly concentrated in band 6–band 9; band 1–band 4; and band 5, band 10, and band 11 after texture transformation (Figure [3\)](#page-5-0). These principal components (PC1–PC3) representing image texture features can reflect soil physical information such as spatial information (i.e., pattern, shape, size, etc.), geometric morphology, texture, and coverage on the soil surface, and have important implications for the basic soil conditions of  $NH<sub>3</sub>$  emissions.

<span id="page-5-0"></span>

Figure 3. Component matrix load value of principal component analysis based on Sentinel-2 L2A **Figure 3.** Component matrix load value of principal component analysis based on Sentinel-2 L2A image.

#### 2.3.2. Air Quality

The air quality in the study area indirectly interfered with soil microbial interaction, affecting soil NH<sub>3</sub> emissions. In order to be consistent with the sampling time of soil NH<sub>3</sub>, the selected time of air quality data was the monthly average of September 2022. Six air quality pollutants (CO, NO<sub>2</sub>, O<sub>3</sub>, PM<sub>2.5</sub>, PM<sub>10</sub>, and SO<sub>2</sub>) were obtained as environmental variables for spatial prediction of NH<sub>3</sub>. The data were obtained from the real-time air quality release system [\(http://218.58.213.53:8081/dyfb\\_air/fb\\_web/dongying.html,](http://218.58.213.53:8081/dyfb_air/fb_web/dongying.html) accessed on

10 November 2022) of Dongying Environmental Protection Bureau, including 40 air quality monitoring stations. The air quality data of all stations were processed using interpolation analysis with a resolution of 10 m  $\times$  10 m in ArcGIS 10.7 software.

#### *2.4. Machine Learning Model*

#### 2.4.1. Random Forest

Random forest (RF) is a tutorial integration algorithm with a decision tree as a base estimator [\[49\]](#page-19-1). In the modeling process of RF, different subsets are randomly sampled from the provided dataset and then used to build multiple decision trees. According to bagging rules, the results of several decision trees were synthesized to predict soil  $NH<sub>3</sub>$  fluxes, that is, the average values of the results output by several base estimators. The learning ability of the RF model is strong, and it can overcome the over-fitting problem caused by a highly dimensional variable input. The RF model has been widely used in soil, ecology, and other fields [\[50–](#page-19-2)[52\]](#page-19-3). The core hyperparameters of the RF model that need to be optimized are shown in Table [2.](#page-6-0) For example, max\_depth and max\_features have a significant impact on the prediction accuracy and splitting depth of the basic estimator.

<span id="page-6-0"></span>**Table 2.** Information description of core hyperparameters of RF model.

#### 2.4.2. GBDT

Gradient boosting decision tree (GBDT) is one of the ensemble ML models that uses classification and regression tree (CART) as the basic model [\[53\]](#page-19-4). Different from the bagging rule of the RF model, the GBDT model meets the basic process of the boosting rule, calculates the loss function based on the results of the previous base estimator, and uses the loss function to affect the next base estimator (Equation (2)) [\[53\]](#page-19-4).

$$
f_n(x) = f_{n-1}(x) + T_n(x)
$$
 (2)

*f*<sub>*n*</sub>(*x*) and *f*<sub>*n*−1</sub>(*x*) represent the *n*-th (*n* ≥ 1) and *n* − 1 weak learners, respectively.  $T_n(x)$  represents a new learner based on the residual of the *n* − 1 weak learner. The current *i*-th learner  $f_i(x)$  in the GBDT model is affected by all previously trained weak learners [\[49](#page-19-1)[,54](#page-19-5)[,55\]](#page-19-6) and finally integrated multiple base estimators and output soil NH<sub>3</sub> prediction values. Because GBDT is optimized in the base estimator, loss function, fitting residual, and random sampling, it has a stronger learning ability than most boosting algorithms. GBDT is one of the most stable machine learning algorithms in actual scenarios. The core hyperparameters and information of the GBDT model are shown in Table [3.](#page-6-1)

<span id="page-6-1"></span>**Table 3.** Information description of core hyperparameters of GBDT model.

Hyperparameters	Type	Range	Explanation
n estimators	int	(90, 120)	Number of trees
learning_rate	float	(0.2, 0.3)	The learning speed
subsample	float	(0.6, 0.72)	The proportion of subsampling
max_depth	int	(5, 10)	The maximum depth of a tree
max features	int, float, string	(2, 16, "log2", "sqrt",	The number of features needed to
		" $auto$ ")	find the best segmentation
min_impurity_decrease	float	(2, 4)	The amount of information gained to consider when splitting nodes

#### 2.4.3. XGB

The eXtreme gradient boosting (XGB) is a new machine-learning model proposed by Chen et al. in 2016. It has been optimized based on the GBDT algorithm, making XGB have better results in dealing with regression and classification problems [\[51,](#page-19-7)[52\]](#page-19-3). As an advanced boosting algorithm, XGB builds the next weak learner based on the results of the previous weak learner in each iteration [\[53\]](#page-19-4). The advantage of the XGB algorithm is that the objective function with a regular term controls overfitting  $[54]$ . In addition, similar to the RF model, XGB also supports column sampling, which extracts some data for training during the iteration process so as to control overfitting by reducing the amount of calculation. Compared with the first-order Taylor expansion of GBDT, XGB adopts the second-order Taylor expansion, which can approximate the real loss function more accurately. Equation (3) shows the objective function  $(O^{(t)})$  [\[51\]](#page-19-7).

$$
O^{(t)} \cong \sum_{i=1}^{n} [L(y_i, \hat{y}_i^{(k-1)}) + g_i f_k(x_i) + \frac{1}{2} h_i f_k^2(x_i)] + \Omega(f_k)
$$
\n(3)

where  $y_i$  and  $\hat{y}_i$  represent the *i*-th measured value and the predicted value at step *t*, respectively, *L* represents the loss function, Ω represents the regular term, *x<sup>i</sup>* and *f<sup>k</sup>* represent the *i*-th input variables and the *k*-th tree, respectively, and *g<sup>i</sup>* and *h<sup>i</sup>* represent the first and second derivatives of the *L*, respectively. Then, the final objective function (Equation (4)) at the *j*-th leaf  $I_i = \{i | q(x_i)\} = j$  is as follows:

$$
O^{(t)} = \sum_{j=1}^{T} \left[ \left( \sum_{i \in I_j} g_i \right) \omega_j + \frac{1}{2} \left( \sum_{i \in I_j} h_i + \lambda \right) \omega_j^2 \right] + \gamma T,\tag{4}
$$

where *T* represents the total leaf nodes of the XGB model,  $\omega_i$  and  $\gamma$  represent the scores on the *j*-th leaf and complexity of leaf nodes, respectively, and *λ* is a compromise parameter that scales the penalty. The core hyperparameters and information of the XGB model are shown in Table [4.](#page-7-0)

Hyperparameters	<b>Type</b>	Range	Explanation
subsample	float	(0.85, 1)	Construct the sampling rate of each tree to the sample
num round	int	(30, 50)	The number of trees
eta	float	(0.2, 0.3)	Learning rate
lambda	float	(0, 4)	Regularization section for processing XGB
min_child_weight	float	(0.1, 2.8)	The sum of weights of the minimum leaf node sample
colsample_bytree	float	(0.92, 1)	The proportion of features used in training out of all features
colsample_bynode	float	(0.95, 1)	Sub-sampling rate of columns split per node
max_depth	int	(1, 4)	Maximum depth of a tree

<span id="page-7-0"></span>**Table 4.** Information description of core hyperparameters of XGB model.

#### 2.4.4. TPE Search Algorithm

Not only is the internal structure of the above prediction model complex, but many hyperparameters also need to be adjusted. Moreover, the hyperparameters have a great influence on the prediction performance of the model [\[55](#page-19-6)[,56\]](#page-19-8). Hyperparameters usually refer to the parameters shared between different modules, functions, classes, or objects in the model. These parameters can be used by multiple components to achieve data transfer, interaction, and sharing of information. The traditional manual adjustment will take a lot of time and cost, and the effect is not good. Studies have shown that compared with the GS algorithm, the Bayesian optimization (BO) algorithm cannot easily plunge the local optimum and is more efficient. Bayesian optimization is considered the most advanced superparameter optimization framework at present and is widely used in various fields

of AutoML [\[57\]](#page-19-9). It uses the frequency of the minimum value to judge. The frequency reflects the probability of the minimum value to some extent. The higher the frequency, the greater the probability that the function has a minimum value. Tree-structured Parzen estimator (TPE) is one of the most advanced BO algorithms based on tree-structured Parzen density estimation. First, the TPE algorithm defines two probability density functions (Equations (5) and (6)) based on  $y^*$  (i.e., the value at the quantile  $r$  in the *y*-set).

$$
r = p(y < y^*)\tag{5}
$$

$$
p(x \mid y) = \begin{cases} l(x) & \text{if} \quad y < y^* \\ g(x) & \text{if} \quad y \ge y^* \end{cases} \tag{6}
$$

Then, the TPE optimization algorithm selects *EI* (expected improvement) as the evaluation criterion (Equation (7)):

$$
EI_{y^*}(x) = \int_{-\infty}^{y^*} (y^* - y) p(y | x) dy = \int_{-\infty}^{y^*} (y^* - y) \frac{p(x | y) p(y)}{p(x)} dy \tag{7}
$$

Finally, we can obtain Equation (8):

$$
EI_{y^*}(x) = \frac{ry^*l(x) - l(x)\int_{-\infty}^{y^*} p(y)dy}{rl(x) - (1-r)g(x)} \propto \left(r + \frac{g(x)}{l(x)}(1-r)\right)^{-1}
$$
(8)

In Equation (8), we can see a direct correlation between the value of *EI* and the value of  $g(x)/l(x)$ . In order to improve *EI*, we make the probability of  $l(x)$  as large as possible and the probability of  $g(x)$  as small as possible so as to select the most suitable x value. In each iteration, the algorithm returns *x* <sup>∗</sup> with the maximum *EI* value, and the returned *x* <sup>∗</sup> will participate in the next iteration so as to repeatedly find the best hyperparameter combination of the soil NH<sup>3</sup> prediction model. In this study, packages (i.e., xgboost, sklearn.model\_selection, sklearn.ensemble, hyperopt, etc.) are imported into the Python 3.9 programming environment to build the above algorithms (i.e., RF, GBDT, XGB, and TPE).

#### *2.5. The Integration Method*

The integration method was used to further improve the prediction accuracy of soil NH<sub>3</sub> flux. First, the residual value  $r_{TPE-ML}(x_i)$  between the true value  $z(x_i)$  of soil NH<sub>3</sub> and the predicted value  $z_{TPE-ML}(x_i)$  of the TPE-optimized ML method (i.e., TPE-GBDT, TPE-RF, and TPE-XGB) was calculated (Equation (9)).

$$
r_{TPE-ML}(x_i) = z(x_i) - z_{TPE-ML}(x_i)
$$
\n(9)

Then, the ordinary kriging (OK) interpolation algorithm was used in ArcGIS 10.7 software to obtain the residual spatial continuity distribution of the TPE-optimized machine learning model. The formula of the OK model (Equations (10) and (11)) is as follows [\[58\]](#page-19-10):

$$
\hat{\gamma}(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} \left[ z(x_i) - z(x_i + h) \right]^2 \tag{10}
$$

$$
\hat{z}_{OK}(x_i) = \sum_{i=1}^{n} \lambda_i z(x_i)
$$
\n(11)

where  $\hat{\gamma}(h)$  represents the experimental semivariogram in the kriging interpolation process, *N*(*h*) represents the number of sampling points separated by *h* (where *h* is the lag distance between  $z(x_i)$  and  $z(x_i + h)$ , and  $\lambda_i$  is the optimal weight. ArcGIS 10.7 software was used to realize the spatial interpolation calculation of the OK model. Finally, the spatial prediction results of soil NH<sup>3</sup> flux in the hybrid geostatistical model were obtained by adding the

$$
z_{TPE-ML-OK}(x_i) = z_{TPE-ML}(x_i) + \sum_{i=1}^{n} \lambda_i z_{TPE-ML}(x_i)
$$
\n(12)

where  $z_{TPE-ML-OK}(x_i)$  includes the comprehensive prediction results of tree-structured Parzen estimator–random forest–ordinary kriging (TPE–RF–OK), tree-structured Parzen estimator–gradient boosting decision tree–ordinary kriging (TPE–GBDT–OK), and treestructured Parzen estimator–extreme gradient boosting–ordinary kriging (TPE–XGB–OK), representing the optimal spatial estimation of soil  $NH<sub>3</sub>$  flux.

#### *2.6. Verification*

In this study, the datasets were randomly divided into 70% for the training set and 30% for the test set to build a prediction method. For accuracy evaluation, root mean square error (RMSE) (Equation (13)) and coefficient of determination ( $R^2$ ) (Equation (14)) were used.  $x_i$  and  $\hat{x}_i$  are, respectively, the real value of soil NH<sub>3</sub> flux and the prediction value of the super parameter optimization model, and  $\bar{x}_i$  and  $\hat{x}_i$  are, respectively, the average of the real value of soil NH<sub>3</sub> at all sample points and the average of the estimated value of the model.

RMSE = 
$$
\sqrt{\frac{1}{n} \sum_{i=1}^{n} (\hat{x}_i - x_i)^2}
$$
 (13)

$$
R^{2} = \frac{\left[\sum_{i=1}^{m} (x_{i} - \overline{x}_{i})(\hat{x}_{i} - \overline{\hat{x}}_{i})\right]^{2}}{\sum_{i=1}^{m} (x_{i} - \overline{x}_{i})^{2} \sum_{i=1}^{m} (\hat{x}_{i} - \overline{\hat{x}}_{i})^{2}}
$$
(14)

Because the ensemble learning models, deep learning models, and other models are extremely complex, abstract, and difficult to understand, the importance score of each environmental variable was output and visualized using the SHapley additive explanation (SHAP) analysis so that we can determine which environmental variables play a leading role in affecting soil NH<sup>3</sup> flux. As a unified interpretation framework, SHAP can calculate the importance score of each feature in the data so as to explain the model. In this study, the SHAP package was imported into the Python 3.9 programming environment to explain the predicted method and visualize the importance of different environment variables.

#### **3. Results and Analysis**

#### *3.1. Statistical Analysis*

Figure [4](#page-10-0) shows the normalized numerical distribution of  $NH<sub>3</sub>$  flux in soil and auxiliary variables. The soil  $NH<sub>3</sub>$  fluxes are concentrated in the median area, and the data structure is normally distributed. PSRI, PC1, and PC2 also showed significant normal distribution. However, the values of other variables showed skewed or bimodal distribution. There were significantly nonlinear characteristics among different environmental variables. The linear correlation between similar variables was strong, the positive linear correlation between vegetation index factors (i.e.,  $SAVI_{red}$  and NDWI, VARI and PSRI, and  $SAVI_{red}$  and PSRI) was high  $(r > 0.2)$ , the negative linear correlation between soil texture factors (PC3 and  $PC1$ ) was strong ( $r = 0.39$ ), and there was a high correlation between air quality variables. Obviously, there was a positive linear correlation between soil NH<sub>3</sub> flux and  $O_3$  (r = 0.21) and a weak linear correlation with other variables. The above correlation analysis results show complex fitting characteristics between soil  $NH<sub>3</sub>$  flux and environmental variables.

Figures 5–7 show the sampling point iteration trend of GBDT, RF, and XGB models Figures [5–](#page-11-0)[7](#page-12-0) show the sampling point iteration trend of GBDT, RF, and XGB models in the TPE optimization process, respectively. Obviously, the sampling points in the TPE in the TPE optimization process, respectively. Obviously, the sampling points in the TPE optimization process have an aggregation trend, and there is a region with the densest distribution of sampling points in each hyperparameter iteration process. For example, distribution of sampling points in each hyperparameter iteration process. For example, some hyperparameters (min\_impuity\_decrease of the GBDT model and min\_child\_weight of the XGB model) increase with the increase in the value, and the distribution of sampling points change from sparse to dense. Other hyperparameters (n\_estimators of the RF model and colsample\_bynode of the XGB model) show the trend of sampling points from dense to sparse (that is, it is difficult to reach the optimal value, even if the hyperparameter value is increased). These sampling-intensive areas are significantly different from the sparse sampling areas, and the optimal parameters often appear near the sampling intensive areas.<br>The lowest RMSE values obtained by the RF, GBDT, and XGB models in the TPE optimization process are relatively close, which are 11.96 kg N ha<sup>-1</sup> d<sup>-1</sup>, 11.77 kg N ha<sup>-1</sup> d<sup>-1</sup>, and tion process are relatively close, which are 11.96 kg N ha<sup>-1</sup> d<sup>-1</sup>, 11.77 kg N ha<sup>-1</sup> d<sup>-1</sup>, and 11.70 kg N ha<sup>-1</sup> d<sup>-1</sup>, respectively, indicating that the TPE algorithm has strong generalha−1 d−1, 11.77 kg N ha−1 d−1, and 11.70 kg N ha−1 d−1, respectively, indicating that the TPE ization in the hyperparameter optimization of different models. TPE always selects the next set of sampling points according to the results of previous sampling points [\[60\]](#page-19-12). After multiple iterations, the probability that the optimal hyperparameters appear in the dense multiple iterations, the probability that the optimal hyperparameters appear in the dense sampling points  $\mu$  in  $\mu$  and  $\mu$ sampling area is much higher than in the sparse area. sampling areas, and the optimal parameters often appear near the sampling-intensive areas.

3.2.2. Prediction Accuracy of TPE–ML Model for Soil NH<sup>3</sup>

The scatter and residual distribution of the measured and predicted values of soil  $NH<sub>3</sub>$ concentration and the regression accuracy of the model are shown in Figure [8](#page-12-1) and Table [5,](#page-12-2) respectively. The spatial prediction accuracies of the TPE-optimized machine learning model for soil NH<sub>3</sub> fluxes are TPE–XGB (RMSE = 8.13 kg N ha<sup>-1</sup> d<sup>-1</sup> and R<sup>2</sup> = 74.22%) > TPE-RF (RMSE = 8.85 kg N ha<sup>-1</sup> d<sup>-1</sup> and R<sup>2</sup> = 71.78%) > TPE–GBDT (RMSE = 10.40 kg N ha<sup>-1</sup> d<sup>-1</sup> and  $R^2$  = 65.90%) (Table [5\)](#page-12-2). The TPE–XGB model had the strongest ability to fit the nonlinear relationship between soil NH<sup>3</sup> flux and environmental variables in comparison with the other models. The residuals of the training sets of the three models satisfy the normal distribution, indicating a better-fitting performance of the models. The scatter distribution of the test set of the TPE–GBDT model is dispersive, and the prediction accuracy is significantly affected by the anomalous samples. In addition, the fitting curves of the residuals of the test

<span id="page-12-0"></span>sets of the three models show left skewness (i.e., the predicted residuals are concentrated in the negative region), indicating that the model predictions are underestimated.

3.2.3. The Semi-Variation Analysis of Residual Values from TPE–GBDT, TPE–RF, and<br>TPE MORMA Furthermore, the spatial semi-variation characteristics of the predicted residuals of TPE–XGB Models

Furthermore, the spatial semi-variation characteristics of the predicted residuals of  $\frac{1}{10}$ indicator used for measuring the spatial variability of the sample points of the sample portant indicator used for measuring the spatial variability of the sample points, usuthe three models were analyzed in ArcGIS 10.7 software. The nugget effect is an im-

ally divided into low spatial dependence (NE  $\leq$  25%) and moderate spatial dependence  $(25\% \le NE \le 75\%)$  [\[61\]](#page-19-13). The NE of the soil NH<sub>3</sub> flux of residual sample points for OK exhibited moderate spatial dependence, making it appropriate for kriging interpolation (Table [6\)](#page-13-0). In the process of semivariogram analysis, the residual sampling points showed a nonuniform distribution, and the semivariogram value (*γ*) tended to be stable as the step size increased. The residual sample points have the highest density (i.e., the strongest spatial autocorrelation) between the distance (*h*) from 0.1 to 0.6 (Figure [9\)](#page-13-1).

## 3.2.4. Spatial Prediction and Mapping Using the TPE–ML–OK Method 3.2.4. Spatial Prediction and Mapping Using the TPE–ML–OK Method

As shown in Table 5, the combined prediction accuracy of the TPE–ML–OK method As shown in Table [5,](#page-12-2) the combined prediction accuracy of the TPE–ML–OK method was higher than that of the monotonic machine learning model, and the three integration was higher than that of the monotonic machine learning model, and the three integration models characterized more than 75% of the spatial variability  $(R^2)$  of soil NH<sub>3</sub> fluxes. Moreover, the test set scattering points of the three integration models were more compactly distributed near the diagonal, and their residuals were closer to normal distribution and distributed near the diagonal, and their residuals were closer to normal distribution and concentrated in the low-value region (Figure [8\)](#page-12-1). The TPE–XGB–OK model exhibited the low-value region (Figure 8). The TPE–XGB–OK model exhibited the highest prediction accuracy (i.e., RMSE = 6.42 kg N ha<sup>-1</sup> d<sup>-1</sup>, and R<sup>2</sup> = 85.97%) in comparison with the other models, which indicated that the TPE–XGB–OK model<br>
in comparison with the other models, which indicated that the TPE–XGB–OK model could explain the linear and nonlinear relationships between soil  $NH_3$  and environmental  $\ddot{\text{m}}$ variables. The above results exhibited that the ML models assisted by the TPE algorithm have a more results exhibited that the ML models assisted by the TPE algorithm have a more uniform distribution of residuals with fewer extremes, and the smoothing  $\epsilon$ effect of residual kriging interpolation promotes the higher prediction accuracy of the TPE–ML–OK mathed TPE–ML–OK method.<br>Figure 10 th case

Figure 10 shows son NH<sub>3</sub> haxes spatially mapped using three integration prediction models. The predicted range of the TPE–XGB–OK model (0.7–82.36 kg N ha<sup>-1</sup> d<sup>-1</sup>) was closest to the range of the true values (1.31–81.89 kg N ha<sup>−1</sup> d<sup>−1</sup>), whereas the mapping closest to the range of the true values (1.31–81.89 kg N ha−1 d−1), whereas the mapping results of the TPE-GBDT-OK model appeared to feature a significant underestimation. The results of the TPE-GBDT-OK model appeared to feature a significant underestimation. spatial mapping results of the three hybrid models were similar, with the TPE–XGB–OK The spatial mapping results of the three hybrid models were similar, with the TPE–XGB– model predicting a more natural spatial excess of soil NH<sup>3</sup> fluxes. Soil NH<sup>3</sup> fluxes in the study area were smaller in the south as a whole, and the areas with larger concentrations were mainly distributed in the central and northeastern of the study area. Especially near  $\frac{1}{2}$  mainly distributed in the central and northeastern of the study area. Especially as  $\frac{1}{2}$ Figure [10](#page-14-0) shows soil  $NH_3$  fluxes spatially mapped using three integration prediction

<span id="page-14-0"></span>

the Yellow River estuary, the high soil NH<sub>3</sub> fluxes may be influenced by river transport effects or soil moisture.

#### **4. Discussion**

#### *4.1. Importance Analysis of Environmental Variables on Soil NH<sup>3</sup>*

SHAP analysis is used to explore the contribution trajectory of environmental variables in the prediction process based on the TPE–XGB model. As shown in Figure [11,](#page-15-0) among the three types of variables of vegetation, air quality, and soil texture, the most significant impact on the spatial variability of soil  $NH<sub>3</sub>$  flux is air quality (i.e., cumulative contribution ratio is 60.52%), followed by vegetation (i.e., cumulative contribution ratio is 30.79%) (Figure [11a](#page-15-0)). Among all the environmental variables,  $O_3$  had the highest contribution to the prediction accuracy of soil  $NH<sub>3</sub>$  (26.29%), and the cumulative importance contribution rate of the first five environmental variables exceeded 70%. The mean SHAP values of other environmental variables such as VARI, PC3, SAVI<sub>red</sub>, PC1, and PM<sub>2.5</sub> were all below 1, which had a low importance on the prediction accuracy of soil  $NH<sub>3</sub>$ . The characterization of the driving force of environmental variables on soil  $NH<sub>3</sub>$  flux at each sample point is shown in Figure [11b](#page-15-0). The SHAP value of the samples with low  $O<sub>3</sub>$  value is negative (i.e., the closer the color is to blue, the smaller the feature value is), and the samples with high  $O_3$  value have positive SHAP values (i.e., the closer the color is to red, the larger the feature value is). That is,  $O_3$  shows a significant positive driving effect on soil NH<sub>3</sub> (i.e., an increase in  $O_3$ ) content in the air will promote the emission of soil NH3). Similarly, NDWI is also positively correlated with soil NH3. Inversely, the SHAP values corresponding to the samples with higher  $SO_2$ ,  $PM_{10}$ , and PSRI values are negative. This result indicates that these variables had a negative driving effect on soil  $NH<sub>3</sub>$ .

<span id="page-15-0"></span>

responding to the samples with higher SO2, PM10, and PSRI values are negative. This result

Figure 11. The SHAP analysis: (a) a standard bar chart obtained using the absolute value of the mean SHAP values of each variable, and (**b**) the SHAP values of the environmental variable in each pling point using the TPE–XGB model. The SHAP value is higher than 0, which means that the sampling point using the TPE–XGB model. The SHAP value is higher than 0, which means that the variable responds to a positive influence on the soil NH<sub>3</sub>; otherwise, it has a negative influence.

# 4.2. The Mechanism of Influence of Environmental Variables on Soil NH<sup>3</sup> *4.2. The Mechanism of Influence of Environmental Variables on Soil NH<sup>3</sup>*

 $A_i = \frac{1}{2}$  fluxes factor affecting factor affecting  $\frac{1}{2}$  fluxes from farmland solid in t Air quality is an important driving factor affecting  $NH<sub>3</sub>$  fluxes from farmland soil in the study area. According to the SHAP analysis, the positive driving effect of  $O_3$  is the most significant. The mechanism of the response of  $\mathrm{O}_3$  on soil N emissions is that it changes soil microbial activity through plant-mediated processes, which may have an important impact on net gas fluxes, because it does not penetrate the soil and has a direct impact on the components of the soil ecosystem [\[62\]](#page-19-14). For example, elevated  $\mathrm{O}_3$  concentrations reduce net photosynthesis [\[63](#page-19-15)[,64\]](#page-19-16) and dry matter accumulation [\[65\]](#page-19-17) by oxidatively damaging plant cell membranes and chloroplasts [63,64,66–69], which in turn alters the soil subsurface processes of plant root respiration and microbial activity [41[,70](#page-19-20)[–73\]](#page-19-21), ultimately affecting the nitrogen (N) and carbon (C) cycles in soil [\[74](#page-19-22)[,75\]](#page-20-0) and greenhouse gas emissions (CO<sub>2</sub>, CH<sub>4</sub>,  $N_2O$ , etc.) [\[76\]](#page-20-1). Recio et al. (2020) found that the high  $O_3$  concentration significantly reduced the absorption of  $NH<sub>3</sub>$  and other emissions from soil by plants [\[9\]](#page-17-8), thereby increasing the emission of some nitrogen gases. For example, the increase in  $O_3$  concentration will significantly increase the peak  $CH_4$  flux of wheat and rice [\[77\]](#page-20-2), and even under the highest  $O_3$  concentration treatment, the cumulative emission of soil  $N_2O$  will double [\[78\]](#page-20-3). With the increase in  $O_3$  concentration, the emission of N element gas also increased, which proved that  $O_3$  was a positive driving force for soil  $NH_3$  in this study.

In addition to air quality variables, soil moisture (NDWI) also had a significant effect on the spatial variability of soil  $NH<sub>3</sub>$  flux in this study. On the one hand, soil moisture has a significant positive effect and sensitivity on soil  $NH<sub>3</sub>$  emission [\[79,](#page-20-4)[80\]](#page-20-5). For example, since soil NH<sub>3</sub> flux is a physical process affected by the concentration of NH<sup>+</sup>-N in soil solution [\[81\]](#page-20-6), the increase in soil moisture will promote the diffusion of  $NH<sub>3</sub>$  in soil, resulting in the increase of soil  $NH_3$  emission [\[79,](#page-20-4)[82](#page-20-7)[–84\]](#page-20-8). On the other hand, soil moisture controls the loss of NH<sup>3</sup> by affecting urea-hydrolyzing microorganisms and urease activity [\[84](#page-20-8)[–86\]](#page-20-9). The increase in the liquid diffusion rate in moist soil is beneficial to the absorption of matrix by microorganisms and promotes the diffusion of  $NH<sub>3</sub>$  in soil (and the emission of soil NH3) [\[87\]](#page-20-10). This is similar to the results of this study. In the estuary area of the Yellow River in the northeast of the study area, due to the dense river network and the high moisture of the farmland soil, the soil  $NH<sub>3</sub>$  concentration is high. In addition, other variables such as soil salinity, soil pH, temperature, and wind speed may also affect soil NH<sub>3</sub> emissions [\[88–](#page-20-11)[91\]](#page-20-12).

#### *4.3. Limitations*

We developed a TPE–ML–OK method with Sentinel-2 remote sensing image and air quality data to predict the spatial distribution of NH<sub>3</sub> in farmland soil. However, this study

has some limitations that should be considered in the future. First, the environmental variables that dominate soil NH<sub>3</sub> emissions under different land use types are significantly different. For example, differences in land cover and land management methods can significantly affect soil  $NH_3$  emissions. The highest total environmental  $NH_x$  concentration in rural areas may be related to intensive agricultural activities (such as fertilization and irrigation) [\[92\]](#page-20-13), while soil pH, mineral nitrogen content, soil temperature, and humidity in the agro-pastoral ecotone play a key role in regulating  $NH<sub>3</sub>$  emissions [\[93\]](#page-20-14).

Second, the high fertilization rate was a significant environmental variable that promoted soil NH<sup>3</sup> emission. The accumulation of chemical fertilizers and organic fertilizers in the soil leads to an increase in the transfer of  $NH<sub>3</sub>$  from the liquid phase to the gas phase and promotes the volatilization of  $NH<sub>3</sub>$  [\[94](#page-20-15)[,95\]](#page-20-16). For example, the high nitrogen fertilizer input will lead to an increase in  $NH<sub>3</sub>$  volatilization, and the more nitrogen fertilizer applied, the more nitrogen loss caused by NH<sup>3</sup> volatilization [\[96\]](#page-20-17), which becomes the main source of ammonia emission increasing in the atmosphere [\[97\]](#page-20-18). On the contrary, the volatilization of NH<sup>3</sup> is limited by washing the fertilizer into the deep soil so that it is adsorbed [\[98\]](#page-20-19).

Third, the influence of meteorological conditions on soil  $NH<sub>3</sub>$  emission should be considered.  $NH_3$  volatilization loss is affected by many factors, such as temperature, precipitation, and precipitation [\[88](#page-20-11)[–91,](#page-20-12)[99\]](#page-20-20). Cold weather is not conducive to the emission of NH3, and strong precipitation may also lead to the removal of ammonia in the soil, resulting in a low concentration of ammonia discharged from the soil [\[97\]](#page-20-18). With the increase in temperature, the initial emission of  $NH<sub>3</sub>$  will increase. When the temperature exceeds the optimum level,  $NH<sub>3</sub>$  volatilization may not be significantly affected by temperature changes. [\[95\]](#page-20-16) Other soil properties also have positive or negative effects on NH<sub>3</sub> emissions. For example, acidic loam is also not conducive to the emission of  $NH<sub>3</sub>$  [\[97\]](#page-20-18); that is, soil pH is positively correlated with NH<sub>3</sub> emission, and soil pH will affect the content of NH $_4^+$ -N in the ammonia conversion reaction system, thus affecting the emission process of soil  $NH<sub>3</sub>$  [\[93\]](#page-20-14). The higher the soil pH, the more  $NH<sub>3</sub>$  volatilization [\[96\]](#page-20-17). The increase in clay content leads to decreased electrical conductivity, which limits the vertical transfer of nitrogen [\[95\]](#page-20-16).

In addition, spatial interpolation is used to obtain the spatial continuity distribution of air quality stations, which is a stable and effective method in small-scale areas. However, in future studies, improving the spatial accuracy of air quality data should be considered in order to further improve its response to the spatial prediction of soil  $NH<sub>3</sub>$  and reduce the uncertainty of prediction. For example, in large-scale areas, the use of aerosol images (such as MODIS and Himawari) and a large number of monitoring station data, combined with machine learning models, can effectively improve the spatial prediction accuracy of air quality, thereby reducing the uncertainty of air quality variables in predicting soil  $NH<sub>3</sub>$  flux.

#### **5. Conclusions**

In this study, we developed an integration method to predict the spatial distribution of NH<sup>3</sup> flux in farmland soil. The GBDT, RF, and XGB models assisted by the TPE algorithm found the optimal hyperparameters, and the probability that the optimal hyperparameters appear in the dense sampling area of TPE iterations. Compared with a single ML model, the three integration models exhibited higher predicted performance for the spatial variability of soil NH<sup>3</sup> fluxes. Moreover, the TPE–XGB–OK model effectively explained the linear and nonlinear relationships between environmental variables and soil NH<sub>3</sub>. The areas with high flux of NH<sub>3</sub> in farmland soil were concentrated centrally and in the northeast. Further importance analysis of environmental variables exhibited that air quality and soil moisture have a significant positive driving effect on soil NH<sub>3</sub>. That is,  $O_3$  promotes soil NH<sub>3</sub> flux by altering the soil subsurface processes of plant root respiration and microbial activity, and soil moisture also has a direct promotion effect on soil  $NH<sub>3</sub>$  emission. In the future, the integration method can be generalized to spatio–temporal fusion prediction, supporting global warming alleviation and high-quality agriculture development in coastal areas.
