Abstract: Hollow fibre membrane contactor (HFMC) technology has been developed for CO_2 absorption primarily using synthetic gas, which neglects the critical impact that trace contaminants might have on separation efficiency and robustness in industrial gases. This study, therefore, commissioned a demonstration-scale HFMC for CO_2 separation at a full-scale anaerobic digester facility to evaluate membrane integrity over six months of operation on real biogas. The CO_2 capture efficiency identified using real biogas was benchmarked at comparable conditions on synthetic gas of an equivalent partial pressure, and an equivalent performance identified. Two HFMC were subsequently compared, one with and one without a pre-treatment stage that targeted particulates, volatile organic compounds (VOCs) and humidity. Similar CO_2 separation efficiency was again demonstrated, indicating limited impact within the timescale evaluated. However, gas phase pre-treatment is advised in order to ensure robustness in the long term. Over longer-term operation, a decline in CO_2 separation efficiency was observed. Membrane autopsy identified shell-side deposition, where the structural morphology and confirmation of amide I and II groups, indicated biofouling. Separation efficiency was reinstated via chemical cleaning, which demonstrated that proactive maintenance could minimise process risk.

Keywords: carbon capture; biogas; prefiltration; membrane fouling; wastewater treatment works

1. Introduction

Anaerobic Digestion (AD) at wastewater treatment works (WWTW) can recover 34% of the initial energy of raw wastewater as biogas [1]. When upgraded to biomethane ($\geq$98% CH_4), it is an energy-dense renewable heat source [2–4]. In the UK by the end of 2017, around 90 sites were producing biomethane, which was primarily facilitated through gas-liquid absorption columns at larger wastewater treatment installations [5,6]. Absorption columns are energy-intensive, requiring up to 0.3 kWh Nm^{-3} biogas [7] and suffer from flooding, channelling and entrainment, which limits their operational range [8]. Hollow fibre membrane contactors (HFMC) are a promising alternative to gas-liquid absorption as the membrane extends the range of operating conditions that can be applied, due to imparting a phase change between the liquid and gas, which eliminates flooding and entrainment [8–10]. The increased interfacial area also introduces a 15-fold process intensification into the absorption column [11,12], reducing the process footprint, capital cost and energy demand.

Whilst much of the HFMC development has been undertaken on synthetic gases, several authors have sought to validate their robustness in an industrial setting with the use of real gases, with particular emphasis on their application to post-combustion carbon capture storage (CCS) [13]. Pilot plant trials by Kværner Process Systems demonstrated

sustained module performance for 7000 h across eight modules employing polytetrafluo-roethylene (PTFE) fibres, with the longest-running module operating for 5000 h [14] on real industrial flue gas from natural gas combustion [15], which evidenced weight, footprint, operational and capital cost reduction versus packed columns [14,16]. Comite et al. [17] applied HFMC to prefiltered industrial flue gases from a coal-fired power station and reported mass transfer data comparable to that derived on synthetic gas, which supports observations of Klaassen et al. [18] who did not observe a reduction in mass transfer over an operating period of 12 months on flue gas. Whilst successful, these examples primarily studied application to gases derived from natural gas combustion, or prefiltered gases where particulates could be expectedly limited. Biogas can be conceived as a more complex gas mixture containing a broad spectrum of trace contaminants including siloxanes, organic halides, microorganisms, terpenes, aldehydes and ketones, ammonia, particulates, pesticides, pharmaceuticals and moisture [19–23]. The introduction of such a complex mixture of trace determinants can be expected to increase the risk of membrane fouling or capillary wetting [24].

Particulate fouling was experienced for a polypropylene HFMC applied to unfiltered flue gas [25], the authors reporting a visible build-up of fly ash on the membrane after 60 h of operation [25], which accords with observations from another study [26–28]. Several studies using both PTFE and PP HFMC have also inferred that gas phase fouling degraded mass transfer when applied to gas comprised of SO_2, fine particulates, H_2O and CO_2 [26,28]. Consequently, whilst several studies report positively on the long-term demonstration in an industrial setting, evidence of deterioration in mass transfer during operation reported by other researchers, suggest there is some discontinuity in the literature, likely due to the changes in the composition of the gas. This is particularly important for biogas, since the gas is ostensibly more complex, yet the evaluation of commercially available membranes for biogas in an industrial setting has been studied significantly less. To our knowledge, Vogler et al. [29] are the only authors to report on the stability of HFMC for biogas upgrading in an industrial setting. Their system comprised potable water as the absorbent and pre-treatment using a carbon filter [29]. An important distinction between flue gas and biogas is also the risk of liquid side fouling by the absorption fluid, which has been observed to block packing media in classical gas-liquid absorption columns due to biological fouling introduced through regrowth, despite the deployment of potable water as the absorption solvent [23]. This study proposes to complement and build upon the limited existing literature on real gases, through implementing a demonstration-scale HFMC system within a full-scale anaerobic digestion facility in order to determine technology robustness for CO_2 separation on real biogas. The specific objectives of the study are to: (i) evaluate the effect of gas-phase contaminants on HFMC robustness through the inclusion and gradual removal of multi-media prefiltration (activated carbon, a molecular sieve and a desiccant) which immediately protects the membrane from particulates, volatile organics and moisture; (ii) evidence the (in)significance of the liquid phase to sustaining the mass transfer of CO_2 from real gas; and (iii) determine the recoverability of membrane performance through standard cleaning protocols, following fouling.

2. Materials and Methods

2.1. Experimental Set-Up

Biogas (CO_2: 34%–39%) produced on-site at an anaerobic digester was redirected from the primary biogas pipeline to the HFMC system post chiller (Figure 1) and gas booster, which removed 'free water' from the gas phase and increased gas pressure to 75 mBar. Due to the low gas pressure following prefiltration (<60 mBar), the gas flow rate was maintained using an inline double-acting flow control valve (F.lli Tognella Spa, Rome, Italy) and manually corrected according to the inlet ST75V Mass Flow Meter (3.4–30 L min^{-1}, error $\pm$ 1.5, Fluid Components International LLC., San Marcos, CA, USA). Gas prefiltration was achieved using VACU-GUARD 150 (Whatman International Ltd., Maidstone, UK) inline filters comprised of activated carbon/PTFE membrane (AC) for particulate and

siloxane removal, anhydrous calcium sulphate/PTFE membrane (ACS) for gas drying and Silica-Alumina zeolite/PTFE membrane (SAZ) as a molecular sieve. Gas and liquid pressure were measured using PX319 series pressure transducers (0–10 BarG, Omega Engineering Ltd., Manchester, UK). Unfiltered or prefiltered biogas flowed on the lumen side of the transverse flow HFMC. The EXF Series 2.5 × 8 inch 3M Liqui-Cel HFMC module (3M Industrial Group, Charlotte, NC, USA) comprised of 10200 microporous polypropylene X-50 fibres, with an outer diameter, inner diameter and fibre length of 300 μm, 240 μm, and 0.16 m respectively. The surface area of each module was 1.2 m^2 based on internal fibre diameter [30].

Potable water was stored in a 1 m^3 IBC tank and applied as an absorbent to the shell side (0.6–9.5 L min^{-1}) in counter-current mode using a centrifugal pump (SP5/A, Lowara, Xylem Water Solutions UK Ltd., Axminster, UK). The liquid flow rate was measured using a FMG90 series electromagnetic flowmeter (Omega Engineering Ltd., Manchester, UK). On-site biogas upgrading was undertaken in a non-controlled environment where ambient temperature (0–30 °C), gas-phase pressure (0–80 mBar) and gas-phase composition (60–63% CH$_4$ *v/v*) all varied. Two identical modules were used to separately study the impact of prefiltration on the gas phase, and the impact of water source on membrane fouling (potable, de-ionised water). To benchmark HFMC performance before and after CO$_2$ separation from real biogas, the HMFC was tested using synthetic biogas (50/50 and 60/40 CH$_4$/CO$_2$) by mixing methane (CH$_4$, 99.995%) and carbon dioxide (99.7%) (BOC gases, Ipswich, UK) using mass flow controllers with two prescribed flow rate ranges (0.01–1.0 L min^{-1} and 0.2–20 L min^{-1}, Roxspur Measurement and Control Ltd., Sheffield, UK) to provide a combined flow rate between 0.05 and 3.5 L min^{-1} at a feed pressure comparable to the real biogas. Absorption solvent (potable water or de-ionised water (15 MΩ)), was stored in an 85 L PVC storage tank. Experimentation on synthetic biogas was undertaken in a temperature-controlled environment (20 °C) with a third module that had been subject to 150 combined hours of on-site biogas upgrading over a period of 150 days, using potable water and de-ionised water to investigate the impact of absorbent on membrane performance. Shell side membrane chemical cleaning was undertaken according to manufacturer guidelines [31] and consisted of a hydraulic cleaning step (75 min contact time, de-ionised water), a biological cleaning step (120 min contact time, 4% (*w/w*) NaOH) a second hydraulic clean (15 min contact time, de-ionised water), an inorganic cleaning step (120 min contact time, 3% (*w/w*) HCl), a final hydraulic cleaning step (75 min contact time, de-ionised water) followed by a 90 min gas drying step.

2.2. Experimental Analysis

Gas composition was determined using inline infrared CO$_2$ and CH$_4$ analysers (BCP-CO$_2$ or BCP-CH$_4$, accuracy <0.5% full-scale, Bluesens gas sensor GmbH, Herten, Germany). Outlet gas flow rate was measured by a QuadraTherm 640i series inline mass flow meter (1–30 L min^{-1}, error ± 1.25%, Sierra Instruments, Monterey, CA, USA) utilising the QMix function to account for changing composition. Carbon dioxide removal was analysed through mass balance [32]:

$$\eta_{CO2} = \frac{[(Q_{G,in} \times C_{G,in}) - (Q_{G,out} \times C_{G,out})]}{(Q_{G,in} \times C_{G,in})}$$

where η_{CO2} is the dimensionless CO$_2$ capture ratio, $Q_{G,in}$ and $Q_{G,out}$ are inlet and outlet gas flow rates respectively (m^3 s^{-1}), and $C_{G,in}$ and $C_{G,out}$ are inlet and outlet gas-phase concentrations respectively (mol m^{-3}). All gas mass flow data were standardised using normalised units (NL min^{-1}). When varying the *L/G* ratio, absorbent flow rate (Q_L) was fixed between 0.2 and 8 L min^{-1}, at each fixed Q_L, Q_G was fixed between 0.05 and 7 L min^{-1}. When maintaining a constant *L/G* at 0.29, Q_L was fixed at 1 L min^{-1} and Q_G at 3.5 L min^{-1}. A GC-MS suite of analytes comprising a range of trace volatile organic compounds (VOCs), total petroleum hydrocarbons (TPH) and gravimetric moisture analysis of raw biogas and prefiltered biogas was undertaken by Lucideon (Lucideon Ltd., Stoke-on-Trent, UK) using

a UKAS accredited methodology. Gas samples were collected in 0.5 L Tedlar bags and activated carbon tubes exposed to 15 L (250 mL min^{-1}) of the sample gas. Moisture content was assessed using gravimetric analysis of pre-weighed silica beads exposed to 15 L (250 mL min^{-1}) of the sample gas. Surface fouling was assessed through solvent extraction (dichloromethane) of volatile organic compounds and GC-MS analysis, undertaken by Northumbrian Water Scientific Services (NWSS, Tyne and Wear, UK) using a UKAS accredited methodology. Fourier transform infrared spectroscopy (Bruker Vertex 70, Bruker UK Limited, Coventry, UK) was used to characterise the functional groups within the fouling layer which was complemented by environmental scanning electron microscopy (ESEM) and energy-dispersive X-ray spectroscopy (EDX) (XL30 ESEM-FEG, Philips/FEI (part of ThermoFisher Scientific, Hillsboro, OR, USA) to determine bound inorganic compounds.

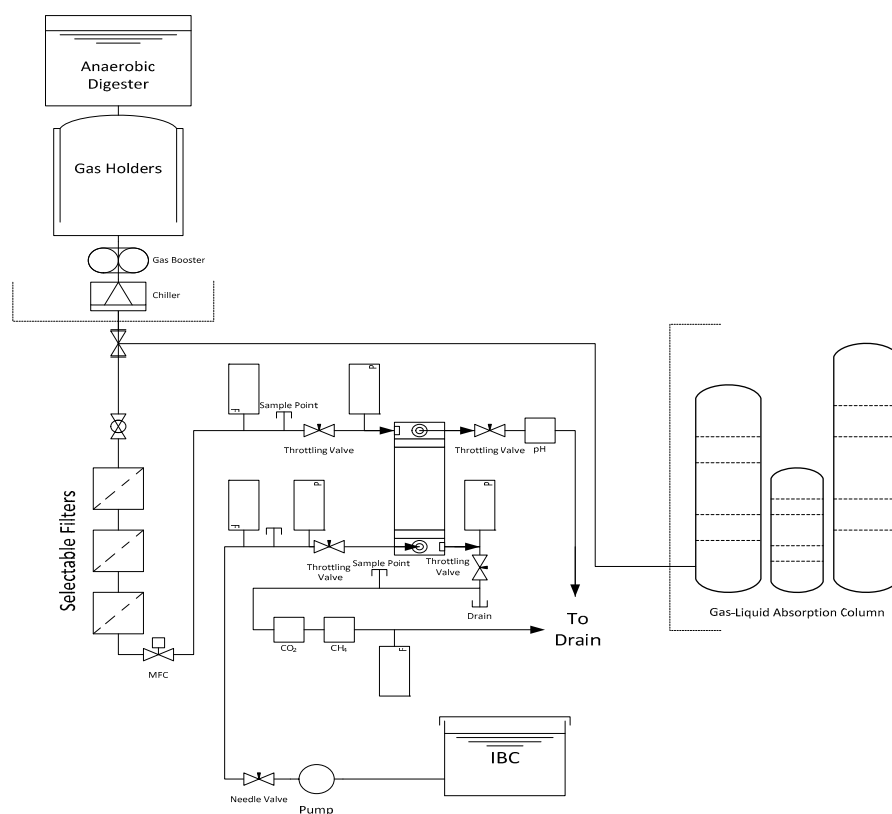

Figure 1. Schematic of experimental set up used for determining CO_2 capture under differing *L/G* set points and integration with existing absorption column upgrading system on-site at a wastewater treatment works (WWTW).

3. Results

3.1. Operational Characteristics

The inlet biogas pressure fixed the gas flow rate to the HFMC, which measured between 10 mBar (Q_G, 3.5 L min^{-1}) and 33 mBar (Q_G, 7 L min^{-1}). For these gas flow rates, the practicable liquid flow rate range was between 0.5 and 9.5 L min^{-1} corresponding to a liquid-to-gas ratio (*L/G* ratio) of between 0.2 and 2.7 (Figure 2). The CO_2 capture ratio (η_{CO2}) was characterised on-site for prefiltered biogas using potable water as the absorption solvent (Figure 2). As the *L/G* was increased, an increase in η_{CO2} was determined. This was comparable to the response observed for synthetic biogas, but a higher η_{CO2} was determined on-site for prefiltered biogas when compared over the same operating range. The average absorbent temperature was 14 °C when on-site, compared to 20 °C when in the laboratory. Consequently, a discrete dataset collected on-site for an absorbent temperature of 20 °C was compared to laboratory data (Figure 2, Inset). A *t*-test for independent samples

yielded t = 0.7, which was markedly below t$_{critical}$ (2.1, *p*-value 0.5), indicating data from real and synthetic biogas is comparable.

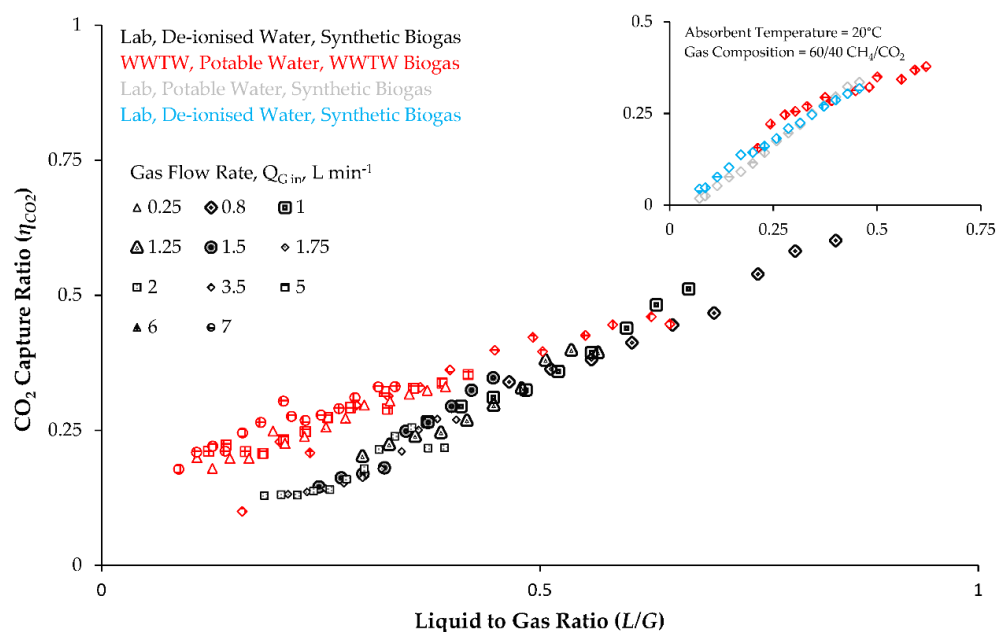

Figure 2. Comparison between CO_2 separation observed with a hollow fibre membrane contactor (HFMC) for synthetic and WWTW derived biogas. On-site: Absorbent, potable water, 14 °C; Q_G was fixed between 0.05 and 7 L min^{-1}, Q_L was then varied between 0.1 and 9.5 L min^{-1} for each Q_G. Lab operation: Absorbent, potable or DI water, 20 °C; Q_G and Q_L varied across equivalent coordinates. Inset: absorbent temperature is on-site is comparable to laboratory conditions, 20 °C; 40/60 CO_2/CH_4 for both lab and WWTW operation.

A HFMC module was operated for an extended period of 115 days at a fixed *L/G* ratio of 0.29 (Q_G, 3.5 L min^{-1}; Q_L, 1 L min^{-1}). During this period, the HFMC was permanently in contact with the absorbent solution and achieved 76 h of cumulative biogas upgrading (Figure 3a). Gaps in data represent time where data were not collected due to periods of non-continuous reporting. After 35 h operation of another HFMC module, gas prefiltration was removed and the membrane subject to approximately 12.5 h operation without prefiltration, equivalent to a gas loading of 2625 L (2188 L m^{-2}) (Figure 2). During this phase, η_{CO2} recorded without prefiltration was similar to that recorded with prefiltration installed. Over the full duration, an average η_{CO2} of 0.17 was determined up to day 115, for the HFMC with prefiltration, after which a progressive decline in η_{CO2} to 0.08 was observed.

3.2. Gas-Phase Characteristics

Trace contaminants were measured through GC-MS analysis (Table 1), which demonstrated considerable concentrations of VOCs (320 mg m^{-3}) and total petroleum hydrocarbons (TPH, 187 mg m^{-3}) within the inlet biogas. Trace contaminant characterisation between discrete prefiltration stages showed that the Silica-Alumina Zeolite (SAZ) molecular sieve was the most effective pre-treatment stage. Solvent extraction of this media, evidenced primary adsorption of octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), which are members of the siloxane family, C12–C14 hydrocarbons, sulphur compounds, terpenes and alcohols.

Following a reduction in η_{CO2} observed on-site after 115 days operation, laboratory evaluation was undertaken to determine whether this could be accounted for by condensation mechanisms on the gas side, where gas moisture content for the inlet biogas approached the dewpoint (~17–19.7 g m^{-3}). The fouled membrane was dried by passing 90 L of CO_2 through the fibre lumen and then subjected to the same hydrodynamic conditions as used on-site, but using synthetic biogas of equivalent concentration (an industrially dry gas) and potable water as the solvent (Figure 4). Comparison of the fouled membrane under site conditions with operation on synthetic biogas demonstrated comparable η_{CO2}, which confirmed a change in module performance rather than gas-phase capillary wetting to be the dominant mechanism for the decline on CO_2 separation efficiency.

3.3. Hollow Fibre Membrane Contactor Fouling Diagnostics

Detailed foulant characterisation was first undertaken using ESEM, where the lumen-side and shell-side of the membrane were both inspected (Figure 5). No particle deposition was evident within the hollow-fibre lumen (example Figure 5b(iii)) where biogas was introduced. This is supported by the FTIR spectra (Figure 6) where no evidence for the adsorption of siloxanes (Si-O bond, 1150–1000 cm^{-1}), carbon disulphide (C-S bond, 700–600 cm^{-1}), or aromatic hydrocarbons was evidenced (C-H bond, 900–690 cm^{-1}) [33]. However, considerable deposition was noted on the shell-side of the hollow fibre membranes, where the absorbent circulated (Figure 5).
Figure 5. Field emission scanning electron microscopy of fibres extracted from HFMC modules: (**a**) virgin fibre exposed to synthetic biogas and potable water only; (**b**) fouled fibre—(i) fibre shell-side, (ii) fibre wall, (iii) fibre lumen-side; (**c**) shell side of fouled fibres using high magnification image (25 μm scale) to evidence extensive shell-side fibre surface fouling.

FTIR analysis of the surface deposition (Figure 6) evidenced two peaks that were distinct from the virgin membrane, and polypropylene reference standards at 1540 cm^{-1} and 1650 cm^{-1}, which are coincident with the amide II and amide I bands respectively, which are two major bands of the infrared protein spectrum. The amide I band is often associated with C=O bond, which relates to backbone conformation of the protein, whilst amide II is indicative of N-H bending and C-N stretching vibration [34]. This is indicative of organic biofouling of the shell-side. To support this assertion, the turbidity of absorbent used for the HFMC (after five days storage) had a turbidity of 29 NTU, compared to potable water stored for the same period that had not been used for biogas upgrading (1.4 NTU), and is complemented by the visual evidence of a green biofouling layer formed at the membrane-absorbent interface (Figure 7). The impact of biofouling on CO_2 separation performance was evidenced by comparing η_{CO2} data from the virgin HFMC first operated on real biogas for biogas upgrading, to that of a virgin HFMC operated on synthetic biogas and finally, HFMC data following 115 days operation (with prefiltration) (Figure 8). The fouled HFMC records η_{CO2} between 25% and 50% of the virgin HFMC (Figure 8). However, once subject to one chemical cleaning intervention of the shell-side, a visible reduction in biofouling was evident (Figure 7). Efficacy of the chemical clean was confirmed by FTIR analysis of the chemically cleaned fibres, which indicated an absence of the amide I and amide II peaks, associated with protein fouling. The impact of this focused intervention (Figure 8) illustrated that it was possible to recover to the expected η_{CO2} using chemical cleaning to target biofouling.
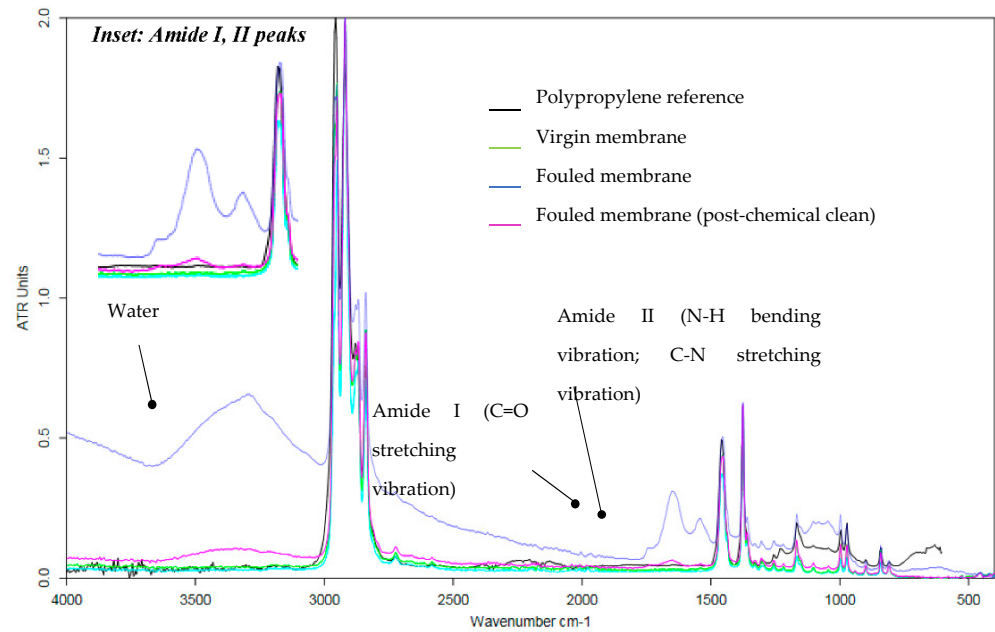

Figure 6. FTIR spectra detailing surface bound functional groups present on polypropylene (PP) hollow fibres pre and post shell-side chemical clean. Additional peaks at 1542 cm^{-1} and 1647 cm^{-1} are attributed to amide II and amide I stretches respectively [34] whilst the stretch from 3100 cm^{-1} downwards is attributed to water [35]. Inset: Close up of spectra between 1500 and 1700 cm^{-1}.

Figure 7. Fouling during dispersive, absorption column and non-dispersive, HFMC gas-liquid contacting. The left-hand photograph of liquid-phase fouling shows from left to right: a chemically cleaned, unused, and fouled membrane, respectively.
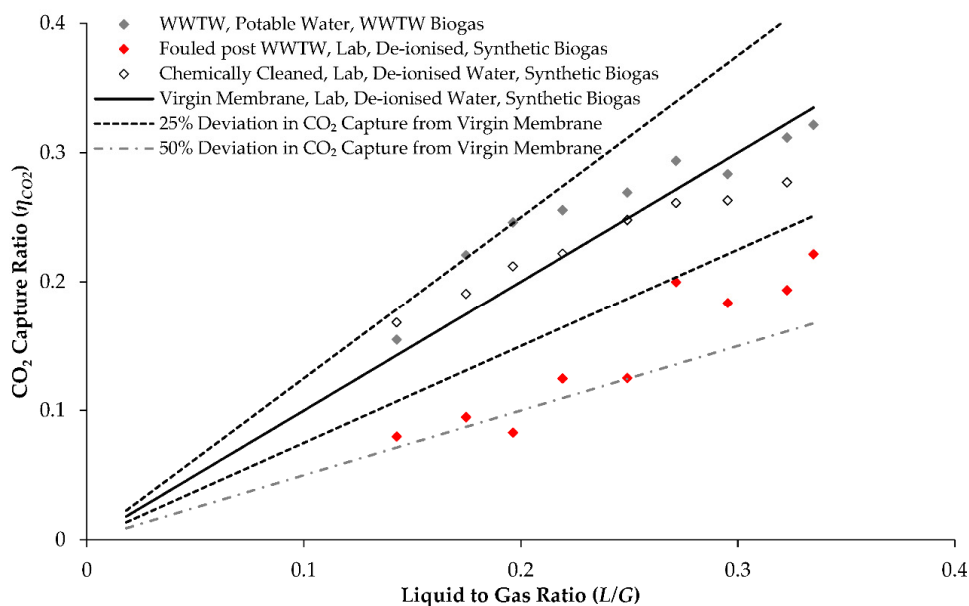

Figure 8. Performance recovery parity of a fouled membrane after chemical cleaning of the membrane shell. Gas flow rate (Q_G) was fixed at 3.5 L m^{-1} and liquid flow rate (Q_L) varied between 0.5 and 1.2 L m^{-1}, inlet gas comprised 60/40 CO_2/CH_4 and P_G 0.5 BarG and potable water at 20 °C. Straight lines represent synthetic data from virgin membrane for comparison; deviations plotted from this data to indicate the impact of fouling and subsequently cleaning of the module.

4. Discussion

In this study, consistent CO_2 mass transfer was identified for HFMC technology when applied to real biogas in an industrial setting, and during a period of steady-state operation, the response in CO_2 capture ratio was comparable to that of synthetic biogas with an equivalent composition (Figure 2). Slight discrimination in responsiveness (the slope identified between *L*/*G* ratio and η_{CO2}) was identified between the synthetic and real data which can be accounted for by the complex and dynamic physical chemistry of both phases in an industrial environment (e.g., density, viscosity, diffusivity and solubility). Importantly, this is in contradiction to observations from HFMC applied to industrial flue gases [25,26,28], where gas phase contaminants, were identified to contribute to fouling, resulting in a loss of CO_2 flux within comparatively short timeframes. Three gas-phase mechanisms are thought to reduce CO_2 flux during industrial operation: accumulation of particulate matter (channel clogging), surface adsorption [26,28] and capillary wetting [24,36]. Particulate accumulation was observed on the gas-side of a HFMC after 7 h exposure to unfiltered industrial flue gas from a coal-fired power station [26–28]. Whilst gas-phase particulates were not explicitly characterised in this study; no particle deposition was observed in the lumen using FESEM following over 76 h exposure (Figure 5b(iii)). This could be attributed to the lower particulate concentration thought to be present in biogas [37], which is supported by the limited impact exhibited when prefiltration was removed (Figure 3). However, some particulate deposition was noted on the prefiltration media, which could indicate the importance of preconditioning industrial gases before use. Trace biogas componental analysis was comparable to the literature on sewage biogas in concentration and speciation [20–22]. The trace siloxanes (D4 and D5) and VOCs identified, possess high octanol-water partitioning coefficients which increase the probability for adsorption to hydrophobic substrates [38]. Surface characterisation by FTIR analysis was unable to determine bond energies characteristic of these compounds on the membrane surface (Figure 6) [33]. This was accounted for by the efficacy of preconditioning with the molecular sieve, which reduced VOCs and TPHs by 69% and 81% respectively. It should be noted that this nevertheless indicates breakthrough of these compounds through the preconditioning filters, which would imply that other mechanisms such as residence time in the

HFMC, in addition to functional characteristics of the membrane surface [39], may also be important in determining the probability for adsorption to the polypropylene hollow fibre membranes. Whilst biogas moisture content approached the dew point of the gas phase; membrane drying did not improve the η_{CO2} (Figure 4). Gas drying has previously been identified as an effective strategy for the recovery of HFMCs that have undergone progressive wetting over a period of 7 d operation [40,41] and would indicate that capillary wetting was not the primary mechanism for the reduction in CO_2 separation efficiency. Upstream preconditioning with the chiller, may have contributed to this since it is employed to reduce the 'free water' concentration of the gas phase to reduce the risk of condensation. Biogas installations typically also comprise of adsorption technology, which may increase robustness if placed upstream of HFMC technology. Importantly, since preconditioning requirements are aligned to those of existing combined heat and power and biogas upgrading installations, the cost of ancillary engineering will not increase through the adoption of HFMC technology.

Evidence for biofouling on the shell-side of the membrane was provided through FTIR analysis, which indicated protein deposition (Figure 6), and FESEM where the presence of an organic foulant layer was shown (Figure 5), which we suggest is the primary mechanism for the 50% reduction in CO_2 flux (Figure 8). Biological fouling has been previously reported within absorption columns for biogas upgrading, deleteriously affecting CO_2 mass transfer through channelling, owing to the growth of methanotrophs (type I and II), gram-negative bacteria, gram-positive bacteria, actinomyces and fungi [23]. Whilst potable water was used as the absorbent the disinfection residual is quickly consumed, permitting colonisation. Biological growth was also evidenced in this study through the increased turbidity in the absorbent, which can lead to fibre clogging on the shell-side, subsequently introducing shell-side channelling which dissipates mass transfer [42,43] and is consistent to the observations of Vogler et al. [29]. Due to the adsorptive potential of biopolymers which can possess strong lipophilic affinity, desorption can expectedly be thermodynamically unfavourable; thus, chemical cleaning methods are preferred to physical methods [43,44]. Polypropylene does not favour oxidants [44] due to their impact upon fibre tensile strength and elongation values [31]. In this study, an alkali-acid chemical cleaning cycle was therefore used and demonstrated almost complete flux recovery, indicating the organic fraction to be strongly reversible (Figures 7 and 8). Comparable biofouling effects observed in full-scale packed columns (the incumbent biogas upgrading technology), result in downtime for reactive maintenance of up to two weeks, which limits asset availability and reduces profitability [23]. Due to the significant reduction in process scale enabled by HFMC, and the relatively low cost of membrane installations [45,46], a duty-standby HFMC system could be implemented to enable the introduction of scheduled proactive maintenance (regular chemical cleaning), to reduce the risk of biofouling through more frequent intervention, whilst ensuring 100% asset availability.

5. Conclusions

In this study, a transverse flow HFMC has been demonstrated for biogas upgrading on real biogas. Mass transfer characterisation, complemented with membrane autopsy, evidenced that HFMCs are robust to impurities within industrially produced biogas. This was confirmed through benchmarking the same HFMC modules with synthetic biogas in a laboratory environment that evidenced comparable CO_2 separation performance for equivalent operating conditions, indicating that HFMC should be scalable from laboratory data, similar to observations for flue gas [17,25]. Operation without prefiltration did not deleteriously impact gas separation efficiency, which is dissimilar to the experience of operating HFMC on industrial flue gases, possibly due to the lower particle concentration. Nevertheless, upstream gas conditioning is recommended to improve robustness, and as this technology is often applied to standard biogas facilities, should not entail additional cost. Shell-side biofouling reduced CO_2 separation efficiency in the longer-term. This is comparable to clogging problems experienced for water scrubbers presently used for biogas

upgrading. Chemical cleaning effectively reversed fouling, which could be introduced proactively to enhance resilience. The low feed gas pressures experienced on-site limited the gas flowrate, which made high CO_2 capture efficiency difficult to achieve. Technology scale-up will inevitably require pre-pressurisation similar to packed columns (around 7 BarG), the success of which has been demonstrated [11,43,47] and would guarantee the process intensification promised by HFMC technology at full scale and demanding considerably lower pressure drops [17,25,29,48–50]. For reference, Vogler et al. [29] evaluated HFMC in an absorption-desorption arrangement at a similar feed pressure to this study (<100 mBar) [29]. Despite the low pressure, the authors reported an energy requirement of 0.3 kWh Nm^{-3} raw biogas which is comparable to the 0.23–0.3 kWh Nm^{-3} reported for gas-liquid absorption columns, indicating that further energy savings can be realised with HFMC through pressurisation [7] making its development toward implementation an exciting proposition.
