1. Hakanson's ecological risk index

The Hakanson's potential ecological risk index (RI) focuses on the toxicity and ecological effects of heavy metals and evaluates the potential ecological risk. The calculation formula used to calculate RI is as follows:

$$E_i = T_i \times \frac{C_i}{B_i} \quad (S1)$$

$$RI = \sum E_i \quad (S2)$$

Where C_i is the measured value, mg/kg, B_i is the soil background value of element i in Jiangsu Province [29], and E_i is the single potential ecological risk index. RI is the total potential ecological risk index. T_i is the toxicity response factor, and the values for each element is Hg=40>Cd=30>As=10>Cu=Ni=Pb=5>Cr=2>Zn=1.

According to Hakanson's ecological risk grading rules [39], the pollution index of potential ecological risk classification is as follows:

| | low | Medium | Strong | Very strong | Extremely strong |
|-------|------|-----------|-----------|-------------|------------------|
| E_i | <40 | 40<E<80 | 80<E<160 | 160<E<320 | >320 |
| RI | <150 | 150<E<300 | 300<E<600 | >600 | |

2. Cumulative prediction model

Based on the current accumulation trend of eight heavy metals and soil remediation in Jiangsu, the concentrations of heavy metals in 2030 and 2050 were predicted under two scenarios: no mutation scenario and optimistic scenario. Setting the year 1973 as a year of zero soil heavy metal pollution, the economy of Jiangsu province developed rapidly since then. As of 2010, soil accumulation of heavy metals had accelerated for 37 years. The year 1973 was determined as a year of zero soil heavy metal pollution, and since then, the economy of Jiangsu has developed rapidly. As of 2010, the accumulation of heavy metals in soil had accelerated for 36 years. After realizing that the soil environment was strongly disturbed by human activities, Jiangsu has initiated a series of soil pollution control efforts. Therefore, the accumulation of heavy metals in soils of Jiangsu accelerated before 2010, and then accumulated at a uniform rate. The acceleration and occurrence rate in heavy metal cumulative prediction model are calculated as follows:

$$A = \frac{2(C_0 - C_B)}{t_1^2 + 2t_1t_2} \quad (S3)$$

$$V = At_i \quad (S4)$$

Where A is the accumulation acceleration; C_b is the soil background value of Jiangsu Province (mg/kg); C_0 is the weighted average values of soil heavy metals in Jiangsu (mg/kg); and V is the current pollution rate (mg/kg/year). t_1 indicates the years of accelerated accumulation of heavy metals (1973-2010), and t_2 indicates the years of uniform accumulation (2010-2021). The heavy metal concentrations were calculated for different scenarios as follows:

Optimistic scenario:

$$C(t) = \begin{cases} C_0 K^t; & C_0 > C_b \\ C_0; & C_0 \leq C_b \end{cases}$$

No mutation scenario:

$$C(t) = \begin{cases} C_0 K^t + VK \frac{(1-K^t)}{(1-K)}; & C_0 > C_b \\ C_0; & C_0 \leq C_b \end{cases}$$

where $C(t)$ is the predicted concentration of heavy metals (mg/kg) after t years, and K is the annual residual rate of soil heavy metals. The annual residual rates of eight heavy metals were calculated based on the soil pollution risk screening value (GB-15618-2018) which takes 100 years to purify to the soil background value in Jiangsu province through natural action [71,86].

K values are shown in the table:

| | Cd | Cr | Ni | Hg | Cu | As | Pb | Zn |
|--------------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|
| K (%) | 0.9856 | 0.9846 | 0.9911 | 0.9826 | 0.9896 | 0.9882 | 0.9879 | 0.9896 |
