Abstract: Background/Objectives: Endometriosis is characterized by the presence of ectopic endometrial-like glands and stroma outside the endometrial cavity, which mainly occurs in the pelvic cavity. Pulmonary endometriosis, or thoracic endometriosis syndrome (TES), describes the rare presence of endometrial-like cells in the thoracic cavity and includes catamenial pneumothorax, catamenial hemithorax, hemoptysis, and lung nodules. Our aim is to summarize the results of all reported cases of TES. **Methods:** Extensive research was conducted through MEDLINE/PUBMED using the keywords “thoracic endometriosis”, “thoracic endometriosis syndrome”, “catamenial pneumothorax”, “catamenial hemoptysis”, and “TES”. Following PRISMA guidelines, all published cases of TES between January 1950 and March 2024 were included. A systematic review of 202 studies in English, including 592 patients, was performed. **Results:** The median age of women with TES is 33.8 years old. The most common clinical presentation is catamenial pneumothorax (68.4%), while lesions are mainly found in the right lung unilaterally (79.9%). Chest computed tomography (CT) was used alone or after an X-ray to determine the pathological findings. Ground-glass opacity nodules and cystic lesions represent the most common finding in CT, while pneumothorax is the most common finding in X-rays. Video-assisted thoracoscopic surgery (VATS) is the main therapeutic approach, usually in combination with hormonal therapy, including GnRH analogues, progestins, androgens, or combined oral contraceptives. Hormonal therapy was also administered as monotherapy. Symptom recurrence was reported in 10.1% of all cases after the treatment. **Conclusions:** High clinical awareness and a multidisciplinary approach are necessary for the best clinical outcome for TES patients. More studies are required to extract safer conclusions.

Keywords: endometriosis; thoracic; pulmonary; extra-pelvic; catamenial; syndrome; TES

1. Introduction

Endometriosis is a chronic inflammatory process which affects approximately 10% of women of reproductive age [1]. It is defined by the presence of both endometrial-like stroma and glands outside the endometrial cavity [2]. Most lesions are located in the pelvis or the abdomen, and thus mainly cause pelvic pain, infertility, and uterine bleeding [1].

Thoracic endometriosis syndrome (TES) is a less frequent clinical entity. Due to the diverse symptoms of TES the exact incidence is challenging to establish. Studies suggest that 1.5% of the population have thoracic involvement of endometriosis [1]. The diaphragm, pleural cavity, and pulmonary parenchyma are affected by these lesions. TES is defined by four clinical entities, which include catamenial hemothorax (CHt), catamenial hemoptysis (CH), catamenial pneumothorax (CP), and lung nodules [3]. CH constitutes a rare entity which is characterized by recurrent hemoptysis during menstruation. The presence of endometrial tissue in the lung parenchyma or bronchus is regarded as the primary cause of this symptom. The pathophysiological mechanisms of intrabronchial or parenchymatic endometrial lesions still remain unclear. Additionally, there is no agreement on the characteristic clinical features or the ideal therapeutic alternatives for patients with lung endometriosis [3].

The aim of the current study is to present the total number of case reports presented in the international bibliography of thoracic endometriosis, and to evaluate their epidemiological features, symptoms, diagnostic methods, treatment procedures, and outcomes.

2. Materials and Methods

A review of the literature was conducted using the PubMed database to identify articles of case reports and case series of thoracic endometriosis. This systematic review was created in accordance with the guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA guidelines). All the articles published between January 1950 and March 2024 that met the inclusion criteria were accumulated in this systematic review. Specifically, our research was performed using keywords, separately and in various combinations, such as lung, pulmonary, thoracic endometriosis, TES, catamenial, hemothorax, hemoptysis, and pneumothorax. This study has not been registered in any public registry.

This systematic review includes patients diagnosed with thoracic endometriosis based on clinical or pathological findings, without specific consideration of the diagnostic methods used. Data from each publication on thoracic endometriosis were extracted and summarized based on the symptoms, the imaging methods utilized and their findings, smoking status, history of pelvic endometriosis, prior gynecological procedures, therapeutic approaches, and any reported recurrences.

The initial research using the aforementioned keywords identified 895 articles. After the removal of duplicates, 885 remained, and by filtering by case reports and case series, 444 studies remained. Furthermore, we checked the references from all articles found, aiming to include any other eligible studies. The remaining articles were screened and 242 were excluded for various reasons, such as irrelevant topics regarding the diagnosis of the case report, insufficient data, or the type of the article (e.g., abstract or review). Publications in non-English languages were also excluded. There were 202 full-text articles assessed for eligibility and none of them were excluded.

Risk of Bias

To minimize the bias risk of the systematic review of case reports and series, we predefined the inclusion and exclusion criteria as outlined previously.

Initially, the bibliography was assembled based on title and abstract by one author, and the full text screening was performed by another author. Two different authors performed the data extraction from the articles that met the inclusion criteria. Data about the age, symptoms, diagnostic methods, radiological findings, history of pelvic endometriosis and surgical history, treatment procedures, and recurrence rates in each article included were

exported to an MS Excel spreadsheet to collect the same information. Two independent reviewers performed double data extraction to reduce the risk of bias assessments, and any disagreements were resolved by a third reviewer.

Some of the limitations manifested in this review are the exclusion of non-English language articles and the inconsistency of some common points among the studies included.

The inclusion process is shown in Figure 1 (PRISMA flow diagram).

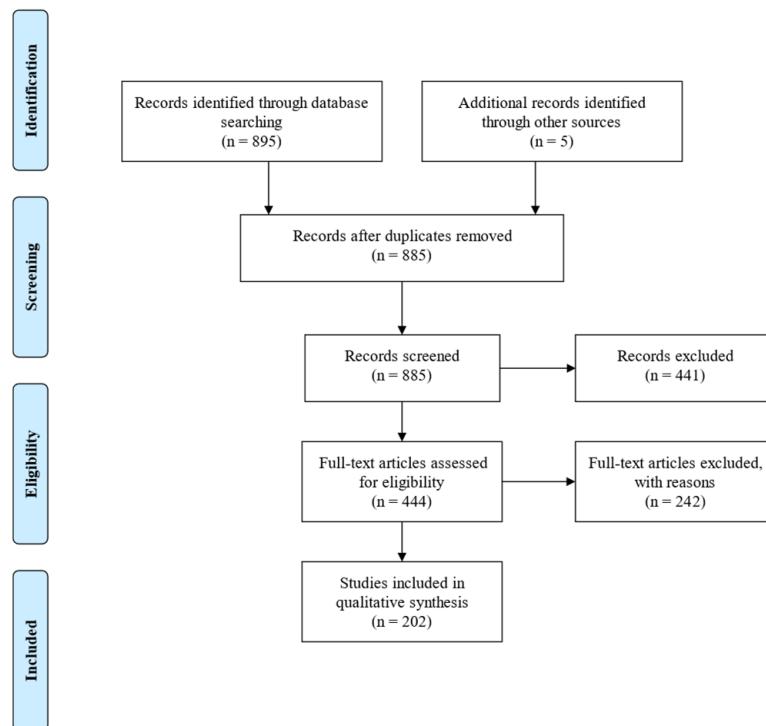

Figure 1. PRISMA flow diagram for the present study.

3. Results

A total of 592 patients with thoracic endometriosis in 202 studies were reported and are listed below. Their main characteristics are reported in Tables 1–7. Their median age was 33.8 years old at presentation, and the most common symptom was pneumothorax (68.4%, 405/592), followed by chest pain (22%, 130/592), dyspnea (20.9%, 124/592), and hemoptysis (14.2%, 84/592). Cough as the main symptom was reported in 6.8% (40/592) of cases and pelvic pain, as a unique symptom, was presented in 2.4% (14/592). Other rare presentations were flu-like symptoms (4/592), shock state (1/592), or absence of symptoms (2/592). The presentation of the symptoms related to thoracic endometriosis is illustrated in Table 1.

In total, 35.3% of the included patients (47/133) were smokers, whereas 6% (8/133) were ex-smokers, and 58.6% (78/133) did not exhibit smoking habits. There is no information concerning smoking in the remaining 460 cases (77.5% of the total patients) (Table 2).

Table 2. Smoking habits of the patients included in the systematic review.

Smoking Habits	Number of Cases (592)	References
Smokers	47	[67,69,70,102,107,111,137,147,164,171,186–190]
Ex-smokers	8	[107,133,135,147,188,191]
Non-smokers	78	[8,9,12,21,22,25,27,28,39–42,46,50,60,61,71,81,84,85,87,92,93,100,101,107,112,114,117,120,121,131,136,140,152,153,161,166,167,174,176,178,180,183,188,192]
Not mentioned	460	[4–7,10,11,13–15,17–20,23,24,26,29–38,43–45,47–49,51–59,62–66,68,72–76,78–80,82,83,86,88–91,94–99,103–106,108–110,115,116,118,119,122–130,132,134,138,139,141–146,148–151,154–160,162,163,165,168–170,172,173,175,177,179,181,182,184,185,190,193–203]

The location of each lesion was determined by radiological, endoscopic, or pathological methods. Most of the lesions (473/592, 79.9%) were found on the right side unilaterally, and specific ectopic endometrial lesions were encountered in 7.6% of the patients in the right lower lobe (RLL) (36/473), in 9.5% of them in the right upper lobe (RUL) (45/473), and in 2.7% in the right middle lobe (RML) (13/473) when mentioned. The lesions, which were only left-sided, were found in 7.9% of the patients (47/592). Lesions in the left upper lobe (LUL), including the lingula, and in the left lower lobe (LLL), were found in 59.6% (28/47) and in 34% (16/47) of patients, respectively. Bilateral lesions were found in 4.9% (29/592). In four patients, the lesions were observed in the trachea [129–131,194], whereas in another one, the location was not stated [109]. Extra-thoracic endometriosis was only detected in 47.8% of the cases (222/464). Tables 3 and 4 summarize the location of the lesions.

Left upper lobe–Lingula	28	[13,14,23,117,131,136,142,151,152,157,168,170,171,173,192,196,197]
Light lower lobe	16	[13,72,115,133,134,144,145,152,156,162,173,178,180,184,187]

On the contrary, 52.2% (242/464) of patients did not show any signs of extra-thoracic endometriosis, and in 21.5% of the total number of patients (127/592), no statement was made in the article (Table 5). The diagnostic tool (transvaginal ultrasonography, MRI, or exploratory laparoscopy) used to identify extra-thoracic endometriosis is not specified for each case.

Table 5. Extra-thoracic endometriosis diagnosed in patients included in the systematic review.

Extra-thoracic Endometriosis	Number of Cases (592)	References
Yes	222	[5–7,12,13,18,21,25,28,30–35,37,40–42,45–48,55–57,59,61–66,69–75,77–80,82,85,86,88,90,93,95,97–102,104–107,109,110,114–116,118,121–123,126,128,134,135,158,159,166,167,183,185,189,190,192,199,200,202,204]

As far as gynecological history is concerned, almost the half of the patients that mentioned their surgical history (53.5%, 212/396) had previously undergone gynecological procedures, including abortions (13.2%, 28/212), diagnostic laparoscopies (23.7%, 50/211), hysterectomies with or without oophorectomies (16.4%, 18/110), and cesarian sections (8.5%, 18/211). Many patients (31.1%, 184/592) had no history of any gynecological surgery

in the past, while for the rest, 33.3% (197/592) of the patients, there is no information about their surgical history. Additional information is provided in Tables 6 and 7.

The imaging methods used for diagnosis were chest X-ray, chest Computer Tomography (CT), chest Magnetic Resonance Imaging (MRI), and bronchoscopy. Chest X-rays were initially used in 189 out of 592 patients (31.9%). The most frequent finding in X-rays was pneumothorax (38%, 72/189), followed by normal findings (20.1%, 38/189), pleural effusion (13.8%, 26/189), consolidation (12.2%, 23/189), and nodules (9%, 17/189). Chest CT scans were most frequently conducted upon clinical symptomatology and at the beginning of the menstrual cycle (32.9%, 195/592). Ground-glass opacities (GGOs) were the most common radiological findings (21.5%, 42/195). Nodules and consolidation were found in 17.9% (35/195) and 10.8% (21/195), respectively. Cystic lesions including cavitary lesions and bullae were found in 15.4% (30/195). Pneumothorax was not so frequently encountered (10.3%, 20/195). Other rare findings included peribronchial infiltrates (2.1%,

4/195), normal findings (5.6%, 11/195), and ring-shaped lesions in only one patient. An absence of pathological findings and disappearance or reduction in the size of the lesions was frequently found in the middle of the menses. MRI and Positron Emission Tomography (PET) were only used in 14 (2.4%) [4–6,72–79,110,132,133] and 4 (0.7%) [7,134,135,186] cases, respectively, in order to confirm the exact position and nature of the lesions. Furthermore, bronoscopies during symptoms were used for diagnosis in 66 out of 592 cases (11.1%). Hemorrhage or hyperemia was observed in 40.9% (27/66) of cases, whereas normal findings were noticed in 42.4% (28/66). Macroscopic lesions were noticed in 11 cases (16.7%), which constituted endobronchial endometriosis. The bronchoscopical lesions disappeared or diminished in size in 14 cases [136–140,187,194,195]. Finally, bronchial angiography was used in five cases (0.8%) in order to detect the site of the hemorrhage [109,111,130,141,142]. The main radiological findings are reported in Tables 8–10.

Table 8. Chest X-ray findings of patients with pulmonary endometriosis included in the systematic review.

Diagnosis of endometriosis was either clinical or pathological. In total, 24.3% (144/592) of cases were histopathologically diagnosed by the presence of endometrial cells or glands. Another pathological finding was the simultaneous presence of endometrial glands, stroma, and hemosiderin-laden macrophages, which occurred in 61 cases (10.3%). Antibodies against CD-10, estrogen, or progesterone receptors were used effectively to diagnose pulmonary endometriosis in 84 cases (14.2%). The pathologist's confirmation was derived from specimens obtained after surgery or bronchoscopy. Histopathological confirmation was derived by the use of bronchoscopy, by the use of bronchial washing or lavage, in six cases (1%). The rest of the patients had a clinical diagnosis. Table 11 summarizes the aforementioned findings.

¹ ER: Estrogen receptor; ² PR: progesterone receptor; ³ CD: cluster of differentiation.

The remaining cases (42.9%, 254/592) were diagnosed based on their clinical presentation with the assistance of radiographic techniques, as mentioned above. The correlation of the radiographic findings with the menses of women aids in the diagnosis of TES.

Thoracic surgical treatment was performed in 276 cases (46.6%). In total, 79.3% (219/276) of these operations were supported by video-assisted thoracoscopy (VATS), while in three cases robotic-assisted thoracoscopy (RATS) was performed. In the majority of cases, lobectomies, segmentectomies, and wedge resections were performed. In 34.4% (95/276), surgeons performed thoracotomies, whereas pleurectomy was performed in 38 patients. In 10 cases, the patients also underwent hysterectomy and bilateral oophorectomy (3.6%), and in thirty-nine cases (14.1%) diagnostic laparoscopy was performed.

Out of a total of 220 patients who received hormonal therapy in combination with the surgical treatment (40.1%), fifty-nine experienced at least one episode of recurrence (26.8%). Patients who received only hormonal therapy (45/549) had a recurrency stated at 33.3% (15/45). Nine patients reported symptoms during hormonal therapy [4,8,9,80–82,135,142,143]. Women experienced recurrence after cessation of the drugs as a result of side effects or a desire for pregnancy in 14 cases [12,27,38,39,44,51–55,142,147,153,196]. The drugs administered to the women as monotherapy or supplementary to the surgical treatment were androgens (41/283, 14.5%), progestins (41/283, 14.5%), gonadotropin-releasing hormones (GnRH), analogues (98/283, 34.6%), and contraceptives (44/283, 15.5%). Fourteen patients did not receive any treatment, whereas in eight case reports the treatment was not mentioned [116,134,168,193].

Minimally invasive techniques were used in nine cases, including three cases of endobronchial laser use, five cases of bronchial artery embolization, and one case of endometrial lesion cryoablation. Three out of five patients treated with bronchial artery embolization had a recurrence, and one out of three patients who underwent endobronchial laser use recurrences. The patient treated with cryoablation showed no recurrence [196]. Fourteen patients initially underwent conservative treatment [87,88,137,144–147,186,188]. Eight of them (57.1%) [145,147,188] presented with symptom recurrences and were treated either hormonally [188] or surgically [188], or spontaneously recovered [145,147].

Information on all therapeutic strategies is shown in Tables 12 and 13.

4. Discussion

Lung endometriosis predominantly affects women between the ages of 20 and 40. In the current systematic review, 202 studies involving 592 patients were included. All the women were of reproductive age, except for two women aged 74 years old, who were receiving exogenous hormones for osteoporosis, and a woman of 51 years old, who was on hormonal treatment due to a past history of breast cancer [13,14]. Two of the patients were pregnant during the diagnosis and the presentation of symptoms of TES [15,112].

The most common symptom by far is catamenial pneumothorax. The symptoms most related to pneumothorax are considered to be catamenial chest pain and dyspnea. Two possible mechanisms seem to be responsible for the development of pneumothorax in lung endometriosis: the rupture of intra-pulmonary blebs, and alveolar damage due to the check-valve mechanism derived from intrabronchial endometriosis or bronchiolar constriction, following excessive production of prostaglandin [208].

Another frequent clinical presentation of TES is catamenial hemoptysis. The cause of hemorrhage is probably an endometriotic implant, either inside a large bronchus or in the lung parenchyma [148]. It is worth mentioning that no massive hemoptysis was reported in any case. The severity of hemoptysis is probably influenced by the biological activity and size of the lesion [188]. However, there is little knowledge on this issue.

As far as the location is concerned, the majority of the implants are right-sided. This may support the theory of the transabdominal–transdiaphragmatic migration of endometrial cells through the right paracolic gutter. This theory requires the existence of passage in the diaphragm between the abdomen and the thorax [205]. Thus, this theory might explain the development of pleural, but not lung, endometriosis [16,17]. In addition, the lower lobes of the lungs seem to be more affected, which supports the theory of microembolization as the pathophysiologic mechanism of lung endometriosis [89,188,206]. Small endometrial tissues cause microemboli in the lung capillaries [149]. This happens as larger quantities of blood circulate in the lower lobes than in the upper ones [89,188].

Previous gynecological procedures might represent a risk factor for the development of this disease [113,150,188]. The most frequent operations were abortions, hysterectomies, and diagnostic laparoscopies. This can occur as a result of the lymphogenic or hematogenous migration of endometrial cells to the pulmonary parenchyma [150]. We should also highlight that the existence of pulmonary endometriosis is not always associated with abdominal or pelvic endometriosis. However, this does not mean that patients with pulmonary endometriosis should not be checked for other endometrial sites.

Most pathological findings reported endometrial glands, stroma, and hemosiderin-laden macrophages. The use of other methods, including immunohistochemistry and anti-estrogen/progesterone receptor antibodies, can be helpful for diagnosis in the case of insufficient endometrial samples. Pseudoinfiltrative patterns without cytologic atypia or microscopic foci inside the bronchovascular bundles with signs of hemorrhage can be found in parenchymal lesions [13]. Endometrial cells can also be found after bronchial washing through bronchoscopy.

A range of diagnostic tests can aid in the differential diagnosis of TES. Beneficial tools include chest radiographs (CXR), CT scans, MRI, and bronchoscopy. The first radiologic examination was usually a chest X-ray. The most common finding in chest X-rays was pneumothorax, followed by consolidation probably due to hemorrhage and lung nodules. Pneumothorax was usually associated with chest pain and dyspnea. Chest CT was the most helpful imaging method for the location of lesions. The radiological findings included ground-glass opacities, consolidation due to hemorrhage, lung nodules, cystic lesions, and pneumothorax. The disappearance of CT lesions during the menstrual cycle favours thoracic endometriosis. MRI was used successfully in order to identify the exact location of the endometrial lesions. Bronchoscopy is not a suitable procedure for distal lesions, although it can reveal sites of hemorrhage [83,132,148,151]. Visible intrabronchial endometrial sites are reported in few cases, including purplish-red or brown submucosal patches in the airways [130,136,152,194]. Even though bronchoscopy cannot histologically confirm the diagnosis, the disappearance of the previous findings in bronchoscopies occurring in the middle of the menses should raise suspicion of endometriosis [140,142,187,195]. Finally, angiography was used in certain cases in order to confirm the exact site of hemorrhaging [109,111,130,141]. The typical findings were prominent vasculature and vascular stains in the absence of endometriosis-characteristic features [109].

The treatment of thoracic endometriosis includes several approaches. Surgical resection can be either used as first-line or second-line treatment after failure or adverse effects

of hormone administration [141]. Video-assisted thoracoscopy and surgery are currently mostly used for the resection of endometrial lesions [18,72,114,153,154]. These include wedge resections and lobectomies. Exploratory thoracotomies and open surgeries can occur when VATS is not effective [19,197]. Surgeries can vary from parenchymal sparing to lobectomies [141,148]. Chest-tube placement is used in cases with life-threatening pneumothorax [17]. Minimally invasive, non-pharmacological treatments with satisfactory clinical outcomes are also reported in the literature. These include bronchoscopical ND-YAG laser treatment and cryoablation through CT guidance [89,152,196]. Bronchial artery embolization failed to treat the patient permanently [89]. The most effective treatment is hysterectomy with bilateral salpingo-oophorectomy [111,134,155]. However, this therapeutic approach should be limited in certain cases due to the multiple side effects of artificial menopause. However, there is a chance of recurrence if hormonal replacement treatment is administrated or partial oophorectomy has been conducted [3,13,148].

Hormone treatment has been used for the management of thoracic endometriosis. The aim of these drugs is to block the ovarian stimulation of the ectopic endometrial tissue [208]. Drugs including oral contraceptives, GnRH agonists, progestin analogs, and androgens have been effectively used for this purpose, as mentioned above. To date, no specific superiority of one drug over the others has been demonstrated, neither in terms of efficacy nor side effects. The drugs mostly used are GnRH analogues and combined oral contraceptives. GnRH agonists cause hypogonadotropic hypogonadism, since they reduce luteinizing and follicle-stimulating hormone [113]. Their side effects are a result of low levels of estrogen and progesterone. Oral combined contraceptives inhibit the secretion of GnRH, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). An androgen frequently used, danazol, leads to anovulation through an increase in blood testosterone and an inhibition of steroidogenesis, but might cause androgenetic side effects or liver damage [207]. Progestins influence the release of GnRH, leading to a decrease in the secretion of FSH and LH [209]. Hypoestrogenism causes the atrophy of ectopic endometrium. The most common side effects are weight gain, hypertension, uterine bleeding, depression, and breast tenderness [141,154,198]. However, hormonal therapy alone seems to be associated with a greater number of recurrences than surgical approaches, based on the data collected by the case reports and the series included in this systematic review. The recurrences are a result of the cessation of the drug due to side effects, and usually do not occur during administration periods [73,84,130,140,141,148,151]. In some cases, a more aggressive approach has been implemented, with both surgical and hormonal treatments (pro- or neo-adjuvant), in order to prevent recurrences and offer the best clinical outcome [18,114,154].

The administration of hormonal drugs renders pregnancy impossible and is associated with various side effects, as mentioned above [141]. Surgery can also have a variety of complications. Furthermore, some support that ectopic endometrial cells do not surely show similar behaviour to normal endometrial tissue towards hormonal influence [147]. No report for massive hemoptysis has ever been published. Thus, conservative treatment has been used as therapeutic approach in this disease. It has been demonstrated that women with mild symptoms show no recurrence of their symptoms without any therapeutic intervention [137,144]. Conservative treatment and follow-up can be a therapeutic approach for these women [147,188]. The ESHRE guidelines recommend the proposal of hormonal treatment in these cases, but if surgery is indicated, the involvement of a thoracic surgeon and/or other relevant specialists is suggested [2].

This review has some limitations: Articles in non-English languages were not included in this study. The use of case series and case reports provides knowledge about this disease. However, these articles do not share many common data points that can be used to extract safe conclusions concerning incidence or cause–effect. Finally, the follow-up periods are short in many studies.

5. Conclusions

It is obvious that pulmonary endometriosis is more frequent than thought. Its main clinical characteristic is catamenial hemoptysis, which coincides with the menstrual cycle of the woman. The radiological disappearance of the lesion in the middle of the woman's cycle is another important point to mention. However, no specific guidelines exist concerning the diagnosis and therapeutic management of these patients. Thus, its prompt management requires a high level of clinical expertise and a multi-disciplinary approach. Finally, it is of paramount importance to create an international registry of patients with clear and common data points, in order to facilitate data extraction and acquire better knowledge of the disease.
