Abstract: The applications of aluminum and its alloys are still limited by low hardness and low wear resistance properties. Surface modifications, such anodizing and plasma electrolytic oxidation, represent a feasible way to overcome these drawbacks. In this study, discs of AA6082 were subjected to the so-called G.H.A. hard anodizing process leading to an anodized layer having a honeycomb-like structure. Samples having alumina layer thicknesses of 10, 50 and 100 µm were subjected to unidirectional dry sliding wear tests, using bearing steel and silicon nitride as counterbody materials. Surface and structure characterization of the samples were performed before and after the tribological tests, using a wide range of techniques; atomic force microscopy and scanning electron microscopy techniques were used before the wear tests. The wear scars were characterized by scanning electron microscopy, energy dispersive spectroscopy and Fourier transform infrared spectroscopy techniques. Results show that the different thickness of the anodized layer does not affect the pores dimensions but has an influence on the micrometric domains in which the pores are divided. These features coupled with the wear test conditions, show to have a strong influence on the wear behavior. The thinnest sample showed also the best performance against the ceramic counterbody.

Keywords: hard anodizing; AA6082; dry sliding; friction

1. Introduction

Aluminum and its alloys are widely used in a variety of industrial fields, owing to their low density, good thermal and electrical conductivity and high strength. However, the practical applications of these materials result in being still limited by major drawbacks like low hardness and poor wear resistance. A feasible way to overcome these issues is to implement processes that modify surfaces, such as anodizing, thermal spraying and plasma electrolytic oxidation.

The aluminum alloys 6xxx series are of particular interest for both the aerospace and automotive industries, owing to the combination of intrinsic properties such as medium strength, formability, weldability and corrosion resistance, coupled with the low cost [\[1](#page-12-0)[,2\]](#page-12-1).

Among all the alloys belonging to the 6xxx series, the precipitation-hardenable medium-strength AA6082 is characterized by an excellent corrosion resistance and shows also the highest strength in the 6xxx series [\[3](#page-12-2)[,4\]](#page-12-3). These peculiar properties coupled with the high strength-to-weight ratio and specific stiffness, are the reasons behind the extensive application of this Al–Mg–Si alloy in automotive, aerospace and shipbuilding industries [\[5–](#page-12-4)[8\]](#page-12-5).

The spontaneous oxidation taking place on the surface of aluminum is the fundamental basic of the anodizing process, involving also a proper temperature level, an electrolytic solution, and the electrical current [\[9,](#page-12-6)[10\]](#page-12-7). During the process, the aluminum piece is placed inside the electrolytic bath and is connected to the positive side (cathode) of a DC power supply, while the anode (negative side) is an inert metal. When the current flows into the circuit, aluminum reacts with the electrolytic bath, building up an Al_2O_3 oxide layer [\[11,](#page-12-8)[12\]](#page-12-9).

The mechanical and tribological properties of the oxide layer obtained by the anodizing process are strongly influenced by the Al_2O_3 porosity and thickness [13-[15\]](#page-12-11). These, in turn, strongly depend on the operating conditions of the anodizing process, such as the cell voltage and the electrolyte composition [\[16–](#page-12-12)[21\]](#page-13-0).

The porosity of the anodic oxide layers was found to be beneficial for tribological applications, being used as a reservoir for lubricants to form self-lubricating structures, enhancing the friction and wear performances [\[22–](#page-13-1)[24\]](#page-13-2). Extensive studies on the wear resistance of filled-in anodic aluminum oxide (AAO), as well as filled-up with solid or liquid lubricants, have been carried out [\[15](#page-12-11)[,25–](#page-13-3)[31\]](#page-13-4), but not many papers deal with the wear properties of anodized aluminum alloys under a dry (non-lubricated) environment [\[14](#page-12-13)[,32](#page-13-5)[–37\]](#page-13-6). It is even harder to find a paper that investigated the dry sliding performance of hard anodized aluminum under medium normal loads (between 1 and 10 N).

Vengatesh et al. [\[38\]](#page-13-7) developed procedures to grow anodic aluminum oxide layers with self-lubricating properties, which were successfully tested under 10 N normal load against stainless steel (301), obtaining the coefficient of friction values always lower than 0.2. Tsyntsaru et al. [\[37\]](#page-13-6) tested the wear and friction behavior of anodic aluminum oxide (AAO) against corundum balls under normal loads ranging from 40 to 1000 mN, with the resulting coefficient of friction values, which vary with the porosity of the anodized layer; the formation of debris layers on top of the anodized surface was also observed. The performance of 1050A and 5754H111 alloys anodized in different conditions were tested by Guezmil et al. [\[32\]](#page-13-5) under a load of 1 N against 100Cr6 counterbodies, showing a complex wear mechanism affected by many factors including the initial morphology of the anodized layer.

Higher loads were tested by Dejun et al. [\[39\]](#page-14-0) against ceramic counterbodies showing the dominance of abrasive wear. Furthermore, Lu et al. [\[40\]](#page-14-1) studied the wear of AA2024 subjected to anodization with a novel acid bath mixture, using 100Cr6 steel as counterbody material under a normal load of 10 N; results show that the surface properties of the anodized layer have a strong influence on the wear and friction behavior of the tested samples. Recently, anodized eutectic Al–Si alloys were tested at higher loads (20 N) against nodular cast iron [\[41\]](#page-14-2), while medium loads (5 N) and corundum balls were used by Benea et al. [\[42\]](#page-14-3) to study the friction and wear performance of anodic films grown using different potential, showing wear rates always lower than 2×10^{-3} mm³/Nm.

In the present study, discs of aluminum alloy 6082 were subjected to a particular hard anodizing process [\[43,](#page-14-4)[44\]](#page-14-5), and their wear performance was characterized through unidirectional dry sliding tests. The surface and microstructure of the samples was characterized coupling different techniques and correlated to the conditions at which the wear tests were performed.

2. Materials and Methods

Disc specimens having a diameter of 20 mm and a thickness of 5 mm made of aluminum alloy 6082 T6 were subjected to the hard anodizing treatment known as G.H.A.® [\[44\]](#page-14-5). The main feature of this method is represented by sealing the $A₁O₃$ layer porosities with silver ions. Moreover, this particular anodizing process creates a compact hexahedral alumina layer organized in a honeycomb-like structure. According to the different anodized layer thickness, samples were divided in three groups: (i) $10 \mu m$ (GHA10), (ii) 50 μ m (GHA50) and (iii) 100 μ m (GHA100), as shown in Table [1.](#page-2-0)

Name	Al_2O_3 Thickness
GHA ₁₀	$10 \mu m$
GHA ₅₀	$50 \mu m$
GHA ₁₀₀	$100 \mu m$

Table 1. Description of the characterized samples.

Surface morphology was detected by means of atomic force microscopy (AFM), using an MFP-3D AFM device (Asylum Research, Goleta, CA, USA); for each sample, regions having a surface area of $1 \mu m \times 1 \mu m$ were inspected.

Microhardness measurements were performed using an applied load of 200 gf using a REMET HX1000 machine (Remet, Bologna, Italy). Each data is the average of five individual measurements.

The friction coefficients were measured using unidirectional dry sliding pin-on-disk wear tests, performed by means of a tribometer (VTHT, Anton-Paar®, Buchs, Switzerland). Tribological experiment were conducted in ambient atmospheric conditions at a room temperature of about 20 ± 2 °C, and at a relative humidity of about 75%. In order to fully characterize the wear behavior of the anodized coatings, two different balls materials were chosen as counterbodies: (i) bearing steel 100Cr6 and (ii) ceramic ($Si₃N₄$). The diameter of the balls was 6 mm. The maximum surface roughness values of the metallic and ceramic balls were $0.032 \mu m$ and $0.014 \mu m$, respectively. The main experimental parameters for the tribological tests were set as follows: (i) 5 N normal load, (ii) 6 mm track radius, (iii) total distance of 250 m, and (iv) a linear speed of 10 cm/s. To ensure the repeatability of the results, three tribotests have been performed for each condition. In order to have an exhaustive characterization of the dry sliding behavior of the samples, very hard $(Si₃N₄$, about 1600 HV) and softer (100Cr6, martensitic, about 700 HV) counterbody materials were used, while the remaining testing conditions were unchanged.

Wear tracks were characterized by field emission gun scanning electron microscopy (FEGSEM) using a FEI (FEI, Eindhoven, The Netherlands) Nova NanoSEM equipped with a Bruker Quantax (Bruker, Hamburg, Germany) energy dispersive spectroscopy (EDS) unit for elemental microanalysis.

The SEM micrographs were obtained collecting the secondary electrons signal and using 5 kV accelerating voltage.

Chemical analysis of the tracks was performed with the Fourier Transform Infrared Spectroscopy (FTIR) technique, using a Perkin Elmer Spectrum 400 spectrometer (Perkin Elmer, Waltham, MA, USA).

The images and profiles of the wear tracks from the 876.6 μ m \times 659.8 μ m surface area were acquired by profilometry analysis using an optical surface metrology system Leica DCM8 (Leica Microsystems, Wetzlar, Germany) with an EPI 20X-L objective. The specific wear rate *W* was calculated using the normal load *N*, the sliding distance *S* and the wear volume *V* [\[45,](#page-14-6)[46\]](#page-14-7), which was calculated using the wear track depth and width information from the profiles examined at the optical profilometer.

3. Results

3.1. Microstructural Characterization

In order to characterize the surface morphology, the three GHA samples, namely the GHA10, GHA50 and GHA100 samples, were investigated by atomic force microscopy (AFM).

The [1](#page-3-0) μ m \times 1 μ m images reported in Figure 1 show remarkable differences among the surfaces of the samples. The surface of the GHA10 sample (Figure [1a](#page-3-0)) shows semi-parallel deep grooves that disappear when the thickness of the anodized layer was increased up to 50 μ m. In fact, on the GHA50 surface (Figure [1b](#page-3-0)) only rounded dimples and bubble-like features were visible. When the thickness of the alumina layer was further increased up to $100 \mu m$, the surface results to be a combination of the peculiarities shown by the first two samples; indeed, a quite smooth surface with small rounded features organized in shallow grooves was present (Figure [1c](#page-3-0)).

In this particular case, the electronic beam was accelerated by a low voltage (i.e., not higher than possible, avoiding the application of a conductive coating. The micrograph in Figure [2a](#page-3-1) shows that the GHA10 samples had peculiar superficial features not detectable on the other samples. The structure of the porous anodic aluminum oxide (AAO) was organized in domains having variable dimensions and a spherical shape. The insets show high magnification details, highlighting the presence of smaller domains (sub-domains) and the characteristic porosity of the anodized samples. In the inset of Figure 2a, a less ordered structure of the domains was visible, owing to the particular features of this sample. As can be seen fr[om](#page-3-1) Figure 2, the porosity did not change remarkably in the three conditions. The mean pore diameter was calculated from the micrographs using stereological methods and the resulting value was 13 ± 2 nm for the GHA10 and GHA50 samples, and 14 ± 3 nm for the GHA100. 3 kV), with the purpose to limit the charge effects and keep the detailed level of the images as high 3 kV), with the purpose to limit the charge effects and keep the detailed level of the images as high as

It is worth to note that the microhardness value of the GHA50 was the lowest, while considering the standard deviations highlighted in Table [2,](#page-4-1) the other two samples show similar values.

It is worth to note that the microhardness value of the GHA50 was the lowest, while considering *3.2. Wear Behavior*

 $(Si₃N₄)$ $(Si₃N₄)$ $(Si₃N₄)$ balls as counterbodies. Figure 4 shows the evolution of the friction coefficient (COF or rather μ as shown in all the graphs) for the three samples sliding against the two counterbody materials, as a
function of the eliding distance Unidirectional dry sliding wear tests were performed using bearing steel (100Cr6) and ceramic function of the sliding distance.

The friction coefficient evolutions reported in Figure [4](#page-5-0) showed remarkable differences in the sliding behavior against the ceramic and metallic counterbodies. The black lines refer to the ceramic sliding behavior against the ceramic and metallic counterbodies. The black lines refer to the ceramic a function of the sliding distance. balls, while those in blue correspond to the metallic ones. The GHA/Si3N⁴ tribo-system showed a typical trend of the friction coefficient, with an initial strong increase (running-in period), followed by a steady-state wear regime, where the COF remained constant. The black curves did not show any remarkable variation along the 250 m of sliding distance and the highest value reached by the friction coefficient was 0.93 for all the tested samples. The GHA/100Cr6 tribo-system showed a running-in period as well at the beginning of the sliding movement, but the following steady-state regime was characterized by a higher instability of the friction coefficient value. This effect was particularly marked when the GHA10 samples slide against the steel counterbodies as reported in Figure [4a](#page-5-0), being the running-in period the longest measured, with a duration of 60 m. It is worth to note that, although the evolution of the COF was quite different for the three samples during the tests against 100Cr6, the average COF values (Figure [4d](#page-5-0)) calculated from the steady state regime were quite similar.

Figure 6. Figure 6. Figure 6. COF) values (**d**). **Figure 4.** Friction coefficient evolution for (**a**) GHA10, (**b**) GHA50, (**c**) GHA10 and average friction

samples against 100Cr6 balls. Upper row (Figure [5a](#page-6-0)–c) shows the overview of the wear tracks at low magnification, while the lower row (Figure [5d](#page-6-0)–f) shows a higher magnification of the scars' details. Figure [5](#page-6-0) shows the FEGSEM micrographs of the wear tracks due to the dry sliding of the GHA

The GHA50 (Figure [5b](#page-6-0)) and GHA100 (Figure 5c) scars were quite smooth and grooves parallel to the sliding direction were visible. The high magnification micrographs of these two samples (Figure [5e](#page-6-0),f) highlighted the cracks formation inside the wear tracks, leading to the fragmentation of the wear surfaces in big flakes. The spotted flakes were smaller in the GHA100 sample (Figure [5f](#page-6-0)), with respect to those in Figure 5e. A peculiar behavior coul[d](#page-6-0) be once again spotted for the GHA10 samples after sliding against the metallic counterbodies (Figure [5a](#page-6-0),d). In this case, a large amount of debris was deposited over the wear track and on its borders, and the high magnification micrograph (Figure [5d](#page-6-0)) clearly showed the presence of a dense layer with a few deep cracks perpendicular to the being the running-in period the longest measured, with a duration of 60 m. It is worth to note that, with to no

The profilometry results obtained for all the tested samples were. detected for the GHA50 and GH100 samples, but not for the GHA10 one. The profilometry results obtained for all the tested samples were used to calculate the wear volume [\[47\]](#page-14-8), which was used to calculate the specific wear rate W (mm 3 /Nm). The results of the wear rate calculations are reported in Figure [9.](#page-8-0)

Figure 9. Values of the specific wear rate calculated for the samples, after sliding against 100Cr6 (blue columns) and $Si₃N₄$ (red columns) counterbodies. columns) and Sian Sian Columns (red columns) content

From Figure 9 it is possible to highlight how the counterbody material had a strong influence on the wear rate of the considered samples. The high hardness of the silicon nitride balls results in a much higher degradation rate of the alumina porous layer, compared to the bearing steel ball, reaching an overall maximum of about 9 mm³/Nm for the GHA50/Si₃N₄ tribocouple. It was not possible to calculate the wear rate of the thinnest sample (GHA10), because when sliding against bearing steel the counterbody adhered to the anodized surface, while during the test with the silicon nitride ball, the wear was negligible (Figure [8a](#page-7-1)).

3.3. Further Insights of the Wear Tracks 3.3. Further Insights of the Wear Tracks 3.3. Further Insights of the Wear Tracks

(FEGSEM) was used, together with the energy dispersive spectroscopy, to clarify the adhesion of the changes and the GHA10 sample (Figure [5a](#page-6-0),d). Given the nature of the backscattered electrons, the contrast of the BSE micrographs is mainly given by the differences in the average atomic number of the elements. Therefore, as shown in Figure [10](#page-8-1) the bright region corresponds to the chromium steel number of the elements. Therefore, as shown in Figure 10 the elements of the bright region corresponds to the σ layer left on the ball trajectory by the counterbody, while the darker area is the GHA surface. Backscattered electron (BSE) signal in the field emission gun scanning electron microscope Backscattered electron (BSE) signal in the field emission gun scanning electron microscope

This result was also confirmed by the energy dispersive spectroscopy (EDS) spectra reported in Figure [10;](#page-8-1) EDS spectrum taken inside the track showed peaks corresponding mainly to the Cr and Fe characteristic energies, while the Al percentage was almost negligible. The EDS spectrum acquired characteristic energies, while the Al percentage was almost negligible. The EDS spectrum acquired outside the wear track highlighted the adhesion behavior of the counterbody material. outside the wear track highlighted the adhesion behavior of the counterbody material.

The backscattered electrons (BSE) signal was also used to investigate the surface of all the samples The backscattered electrons (BSE) signal was also used to investigate the surface of all the having flakes with similar features inside the wear tracks. As already known [\[48](#page-14-9)[,49\]](#page-14-10), when α -Al₂O₃ is exposed to high levels of humidity (75%, higher than the typical indoor values of 20-40%), the formation of aluminum hydroxide is likely to take place. In particular, the Al–O–OH form, already known as boehmite, has been found in previous works [\[50](#page-14-11)[,51\]](#page-14-12). The BSE signal can be used to have evidence of the formation of this compound along with the flake generation.

Figure [11](#page-9-0) shows the BSE micrographs of the GHA50/Si₃N₄ (Figure [11a](#page-9-0)) and GHA100/100Cr6 (Figure [11b](#page-9-0)) samples, which were taken as representative examples of the overall situation. The darker (Figure 11b) samples, which were taken as representative examples of the overall situation. The region could be identified as aluminum hydroxide, while the brightest part of the micrographs was alumina. These results are in agreement with those of the aluminum hydroxide formation theory, was alumina. These results are in agreement with those of the aluminum hydroxide formation theory, already reported in literature [\[50,](#page-14-11)[51\]](#page-14-12). already reported in literature [50,51].

4. Discussion

 $\overline{\text{GHA100}}$ were prepared by hard anodization [\[44\]](#page-14-5). Samples having anodized layer thickness of 10 μ m (GHA10), 50 μ m (GHA50) and 100 μ m

The surfaces were investigated by means of atomic force microscopy (AFM) and field emission gun scanning electron microscopy (FEGSEM), whose results, shown by Figures [1](#page-3-0) and [2,](#page-3-1) demonstrated that by varying the thickness of the anodized samples, it is possible to modify the surface of the samples. Figure [1](#page-3-0) highlights that while the GHA100 samples shows, at a micrometer level, surface features that can be described as a combination of those of the other two samples (GHA10 and GHA50), the GHA10 (Figure [1a](#page-3-0)) was the only one where circular elements were missing. As can be seen in Figure [2](#page-3-1) the GHA10 sample also shows an irregular arrangement of the micrometric domains in which the pores were divided throughout the surface; furthermore, as highlighted in the inset of Figure [2a](#page-3-1), in some areas of the sample's surface the porous structure seemed to collapse.

During hard anodization in order to increase the thickness, it is necessary to increase the time duration of the anodization process [\[43\]](#page-14-4). This did not affect remarkably the density and the dimensions of the pores [\[42\]](#page-14-3), as suggested also by Figure [2](#page-3-1) and its insets. In the considered samples what was changing remarkably was the arrangement of the micrometric domains, or rather the above-mentioned honeycomb-like structure typical of the GHA process [\[44\]](#page-14-5). The FEGSEM results of the surface inspections highlight that the duration of the anodization process to obtain a 10 μ m thick alumina layer was too short to let the micrometric domains organize themselves (Figure [2a](#page-3-1)) in the most appropriate configuration, as those reached by the other samples (Figure [2b](#page-3-1),c). These peculiarities $\frac{1}{2}$ configuration, as the sample configuration, as the other samples (Figure 2b, c). The samples (Figure 2b, c). seemed to have a strong impact on the sample's behavior, during the dry sliding under the chosen
wear testing conditions wear testing conditions.

As can be seen in Figure [4,](#page-5-0) indeed, the friction coefficient evolution shows a number of spikes, not spotted in the other measurements; the sliding resulted in the formation of the tribo-chemical layer dobserved in Figures [5a](#page-6-0) and [6a](#page-6-1), causing a decrease of the friction coefficient to a steady-state sliding regime. The tribolayer formation was due to the counterbody adhesion on the alumina surface, and its composition was obtained by energy dispersive spectroscopy investigations, whose spectra are reported in Figure [10.](#page-8-1) The formation of tribo-chemical layers and their positive effect on the friction has been already reported by Kim et al. [\[14\]](#page-12-13), during the study of nanoporous anodic aluminum oxide (AAO) reciprocating against steel balls (440C bearing steel) in dry sliding conditions, under high loads (0.1 N and 1 N). As can be seen in Figure [5a](#page-6-0), the adhesion of the counterbody to the sample surface led μ the steady state year regime, shows terminal only by small peaks related to the delemination of the counter to the steady-state wear regime, characterized only by small peaks related to the delamination of the
tribe shemical layer \overline{a} tribo-chemical layer.

As observed by Malayoglu et al. [\[35\]](#page-13-8) the formation of a tribolayer can be correlated with the asperities on the surface of the samples, providing the favorable conditions for the counterbody material adherence to the surface, owing to mechanical interlocking phenomena. The use of silicon nitride counterbodies under the same experimental conditions (Figure [5\)](#page-6-0), highlighted the lack of tribo-chemical reactions at the ceramic/ceramic interface, despite the morphological features of the samples. Moreover, the hardness (1600 HV) of the silicon nitride counterbodies, considerably higher than that of the anodized samples (Table [2\)](#page-4-1), results in a much higher degradation rate of the alumina porous layer (Figure [9\)](#page-8-0), particularly remarkable for the sample having the lowest hardness overall (GHA50). The flakes generation inside the wear track was observed for all the samples (Figures [5](#page-6-0) and [7\)](#page-7-0), except for the GHA10/100Cr6 tribo-couple.

The formation of aluminum hydroxide, reported in Figure [11](#page-9-0) and proved by the FTIR results in Figure [12,](#page-10-0) was found to be responsible for the flakes formation and showed to have a positive influence on the tribological properties of the samples, given its effect of limiting or rather avoiding the formation of cracks inside the wear tracks. The aluminum hydroxide formation during the α -Al₂O₃ dry sliding under high humidity conditions, firstly observed during the 90s [\[50,](#page-14-11)[51\]](#page-14-12) has been recently studied by Lee et al. [\[52\]](#page-14-13) in tribotests performed under conditions like those used in the present study. The flake formation suggested that fracture and delamination of the coating seem to be the main wear mechanism.

Other studies reported in the literature from Yerokhin et al. [\[53\]](#page-14-14) and Guezmil et al. [\[54\]](#page-14-15) reported that anodic oxide coatings with low thicknesses are more effective in terms of friction, scratch and impact resistance. From the results highlighted in this paper, in terms of wear rate the GHA10 samples shows to have the best overall performance while sliding against the ceramic counterbody, since wear volume was so small to make the wear rate negligible. During the dry sliding test against the steel counterbody, the tribochemical reactions taking place at the interface between the anodized surface and the counterbody were the most influential parameter, since it caused adhesion in the case of the GHA10 sample (suggesting a link with the unique surface features of this sample). On the other hand, comparing the performance of the other two samples, the best overall behavior against 100Cr6 balls was ascribed to the thickest anodized sample (GHA100), probably due to the higher microhardness of the latter with respect to the 50 µm thick layer (GHA50).

The tribo-chemical reactions taking place during the dry sliding of the counterbodies on the anodized samples, due to the humidity and local temperature conditions, resulted in being enhanced by the morphological features of the anodized layers. This affects all the studied tribocouples and allows us to highlight the peculiar performance of the considered samples, which could expand their range of applicability.

5. Conclusions

The present paper investigated the wear resistance response of hard anodized aluminum, under unidirectional dry sliding conditions. Samples having alumina layer thicknesses of 10, 50 and 100 µm corresponding to the GHA10, GH50 and GHA100 names, obtained with the process reported in Reference [\[38\]](#page-13-7), were subjected to wear tests in a pin-on-disk apparatus, using bearing steel (100Cr6) and ceramic (S_iS_A) balls as counterbodies. The tribo-test results were correlated with the induced surface modifications. The main conclusions can be listed as follows:

When sliding against the bearing steel counterbody, the GHA10 sample shows the formation of a tribo-chemical layer, due to the adhesion of the counterbody material to the samples surface. On the other hand, the 50 μ m (GHA50) thick sample showed a better performance compared to the thickest one (GHA100).

The dry sliding against the ceramic counterbodies resulted in a much higher degradation rate of the anodized layer with respect to the bearing steel balls, with the worst overall performance in terms of wear rate given by the GHA50 sample. This effect was ascribed to the lower hardness of this sample, while the thinnest anodized layer (GHA10) had the best performance with a negligible wear rate.

The results reported in the present paper show that the friction and wear behavior, as well as the wear mechanisms of the considered G.H.A. hard anodized AA6082 samples, were quite complex and varied strongly with the testing conditions. However, the superior performance of the sample with the thinnest anodized layer (GHA10), under the most demanding wear test (against $Si₃N₄$) requires further understanding since it could open interesting scenarios to foster the applicability of this peculiar anodization process.
