Abstract: In the continuous casting process, the shrinkage of the peritectic phase transition during the initial solidification process has an important influence on the surface quality of peritectic steel. The initial solidification process of 0.10C%, 0.14C%, and 0.16C% peritectic steels was observed in situ by a high temperature laser confocal microscope, and the contraction degree during initial solidification was characterized by surface roughness. The results showed that under the cooling rate of 20 ◦C/s, the surface roughness value *R*a(δ/γ) of 0.10C% peritectic steel was 32 µm, the *R*a(δ/γ) value of 0.14C% peritectic steel was 25 μm, and the $Ra(\delta/\gamma)$ value of 0.16C% peritectic steel was 17 μm. With increasing carbon content, the contraction degree of the $\delta \rightarrow \gamma$ transformation decreased, and the value of the surface roughness *R*a(δ/γ) declined. Therefore, surface roughness can characterize the contraction degree of the $\delta \rightarrow \gamma$ transformation in the initial solidification process of peritectic steel under the condition of a large cooling rate.

Keywords: peritectic steels; phase transformation; contraction; surface roughness; continuous casting

1. Introduction

The surface quality of hypo-peritectic steel has been a long-term research topic in continuous casting technology. Early research on slabs showed that hypo-peritectic steel with a carbon content of 0.09–0.18% was prone to longitudinal cracks. To discover the reason behind the longitudinal cracks, researchers have focused their attention on the $\delta \rightarrow \gamma$ phase transformation of these steels [\[1–](#page-8-0)[3\]](#page-8-1). During the initial solidification process of hypo-peritectic steel, the inhomogeneous air gap between the shell and the wall of the mold is caused by the contraction of the $\delta \rightarrow \gamma$ transformation, resulting in uneven heat transfer between the shell and the mold, leading to a nonuniform stress distribution inside the shell. Under the effect of thermal stress, friction force, hydrostatic pressure, etc., the weakness of the shell can easily cause the formation and development of cracks $[4-6]$ $[4-6]$. With increases in the productivity and hot-rolling rate, the surface cracks of hypo-peritectic steel slabs become stubborn defects that affect the production of continuous casting [\[7–](#page-9-2)[9\]](#page-9-3). Therefore, it is of great scientific and practical significance to study the degree of shrinkage of the peritectic phase transition during the initial solidification of hypo-peritectic steel.

Matsumiya et al. [\[10\]](#page-9-4) calculated the stress and strain of free shrinkage with different carbon content steels during the solidification process and pointed out that the tensile stress of the 0.14C% steel shell reached maximum value. Jablonka et al. [\[11\]](#page-9-5) calculated the relationship between the carbon content and the shrinkage of the shell under different degrees of undercooling. However, there is a big gap between the mathematical model and the actual solidification process of steel. Therefore, researchers have designed a variety of high-temperature laboratory experiments, such as dipping

test experiments [\[12\]](#page-9-6), the molten steel droplet method [\[13,](#page-9-7)[14\]](#page-9-8), differential scanning calorimetry [\[15\]](#page-9-9), and the submerged split chill tensile test method [\[16\]](#page-9-10), to simulate the solidification process of steel in continuous casting, hoping to verify the results of the mathematical models. However, none of the abovementioned experimental methods could obtain the degree of undercooling and cooling rate during the solidification of the shell, and their results regarding the relationship between the shrinkage degree and the carbon content lacked the background condition, such as the degree of undercooling and cooling rate.

Shibata et al. [\[17\]](#page-9-11) and Dippenaar et al. [\[18\]](#page-9-12) simulated the solidification process of peritectic steels using high-temperature laser confocal microscopy and studied the effect of the cooling rate on the peritectic transformation. Their results indicated that the peritectic $\delta \rightarrow \gamma$ transformation process was accompanied by the generation of surface wrinkles. When the cooling rate was 20 K/min, if the carbon content approached 0.10C%, the displacement velocity of the δ/γ boundary increased synchronously. Additionally, the interface displacement velocity was related to the shrinkage degree of the peritectic δ \rightarrow γ transformation. However, the cooling rate in the above experiment was significantly lower than the maximum cooling rate in the meniscus region of continuous casting. Griesser et al. [\[19\]](#page-9-13) suggested that as the degree of undercooling increased, the peritectic transformation process evolved from a planar to a dendrite-like transition and eventually became a massive-type transformation. When the $\delta \rightarrow \gamma$ transformation is performed in a massive-type mode, the γ/δ interface displacement velocity cannot be measured.

Guo et al. [\[20\]](#page-9-14) proposed the use of surface roughness $Ra(\delta/\gamma)$ to characterize the degree of peritectic $\delta \rightarrow \gamma$ transformation. Under the cooling condition of 20 °C/s, the surface roughness of the steel sample changed significantly after the peritectic $\delta \rightarrow \gamma$ transformation. The value of the surface roughness *Ra*($δ/γ$) correlated to the shrinkage degree of peritectic $δ \rightarrow γ$ transformation. This method can characterize the shrinkage degree of the $\delta \rightarrow \gamma$ transformation under large cooling conditions. However, this method has not been applied to study the effect of carbon content on the shrinkage degree of peritectic $\delta \rightarrow \gamma$ transformation under large cooling conditions.

In order to study the effect of carbon content on the contraction degree of $\delta \rightarrow \gamma$ transformation under a large cooling rate, this paper characterized the contraction degree by surface roughness. Through in situ observations of the $\delta \rightarrow \gamma$ transformation process at 20 °C/s, we measured the surface roughness *R*a(δ/γ) values of 0.10C%, 0.14C%, and 0.16C% peritectic steels using high temperature laser confocal microscopy. It is hoped that the research results can provide boundary conditions for the calculation model to measure the quantitative relationship between the contraction degree of the peritectic phase transition and the surface roughness under a large cooling rate.

2. Materials and Methods

2.1. Materials

In order to study the effect of carbon content on the degree of peritectic $\delta \rightarrow \gamma$ transformation shrinkage under a large cooling condition, 0.10C%, 0.14C%, and 0.16C% hypo-peritectic steels were selected as the experimental steel samples. The chemical compositions of the steel samples were analyzed through optical emission spectrometry (Table [1\)](#page-1-0).

Steel	Chemical Composition (mass%)											
		Si	Mn	Al	S	P	Ni	Cr	Ti	Fe		
S ₁	0.10	0.250	1.22	0.049	0.001	0.011	0.120	0.179	0.017	bal.		
S ₂	0.14	0.250	1.25	0.035	0.002	0.015		0.116	0.014	bal.		
S ₃	0.16	0.250	1.17	0.033	0.002	0.012	0.120	0.120	0.016	bal.

2.2. Confocal Scanning Laser Microscope (CSLM) 2.2. Confocal Scanning Laser Microscope (CSLM)

A Yonekura VL2000DX-SVF17SP confocal scanning laser microscope (CSLM) (Lasertec, Yokohama, A Yonekura VL2000DX-SVF17SP confocal scanning laser microscope (CSLM) (Lasertec, Japan) was used to heat and cool the steel [\[21\]](#page-9-15). The most important feature of the CSLM is the ability to perform in situ observations of the steel during the melting, solidification, and cooling processes. The heating furnace is the core part of the CSLM (effective heating area: $10 \text{ mm} \times 10 \text{ mm}$, heating temperature range: 50–1800 °C, maximum heating rate: 10 °C/s, maximum cooling rate: 100 °C/s), which is controlled by the temperature system and monitored in real time. Based on the above advantages, CSLM has been used by many researchers to scrutinize the solidification process of steel in situ [\[17–](#page-9-11)[20\]](#page-9-14). A standard objective lens was used to measure the surface roughness (*Ra*) with the corresponding computer software (NIS-Elements C, Yokohama, Japan) to obtain the 3D image information of the samples through a CSLM. information of the samples through a CSLM.

The experimental steel slab was cut into cylindrical specimens with a diameter of 7.8 mm and a height of 2.5 mm, then sanded and polished with sandpaper. Using CSLM to simulate the solidification process of the sample, the thermal scheme of the steel sample is shown in Figure [1.](#page-2-0) The temperature of the steel sample was raised from room temperature to $T_{\rm L}$ + 30 °C with a rate of 10 $°C/s$, which was then was held for 1 min to ensure the complete melting of the steel sample. Where T_L represent the melting temperature of the steel sample. Next, a quick cooling rate of 20 °C/s was applied to cool the samples to 1200 °C. Finally, the sample was cooled to room temperature with a cooling rate of $1 \textdegree C/s$. The cooling air was high purity argon (6 N) and a video was recorded at 20 frames per second during the cooling process. The heating system was turned off, and then the frames per second during the cooling process. The heating system was turned off, and then the surface roughness of the solidified steel samples at room temperature was measured using a laser surface roughness of the solidified steel samples at room temperature was measured using a laser confocal microscope. confocal microscope.

When measuring the surface roughness of the steel multipoint measurements.

Figure 2. (a) the surface morphology of the sample; (b)the surface at high magnification; (c) the roughness measurement process diagram. roughness measurement process diagram. roughness measurement process diagram.

In order to verify the accuracy of the surface roughness, 0.54C% high carbon steel was selected as the reference steel. There is no $\delta \rightarrow \gamma$ transformation in 0.54C% high carbon steel, so the surface roughness can only be caused by the low temperature phase transition. Figure [3 s](#page-3-1)hows the surface measurement area of the 0.54C% high carbon steel. The blue arrow shows the direction of the surface wrinkles. Guo et al. [[20\]](#page-9-14) made the measurement line perpendicular to the direction of the surface wrinkles, as seen a-1-a-3 in Figure [3.](#page-3-1) The results of the a-method are displayed, where the value of surface roughness Ra was $10.43 \mu m$. However, when the surface roughness measurement line was along the direction of the wrinkles (measurement line "b", for example), the value of the surface roughness *R*a was less than 1 μm. roughness *R*a was less than 1 µm. roughness *R*a was less than 1 μm.

$$
Ra_{(\delta \to \gamma)} = Ra - (Ra_{(\gamma \to \alpha)} + Ra_{(\gamma \to \alpha + \text{Fe}_3\text{C})})
$$
\n(1)

According to the results of Guo et al. [20], the surface roughness of peritectic steel was influenced by the $\delta \rightarrow \gamma$ transformation in the high temperature range and the $\gamma \rightarrow \alpha$, $\gamma \rightarrow \alpha$ + Fe₃C transformation in the low temperature range. Additionally, the $\delta \rightarrow \gamma$ transformation surface roughness $Ra(\delta/\gamma)$ of peritectic steel can be calculated by Equation (1) [\[20\]](#page-9-14). As described earlier, when measuring the surface roughness of 0.54C% high carbon steel by the b-method, the value of the surface roughness was less than 1 μ m. Therefore, the b-method could avoid the influence of low-temperature phase transformation $(\gamma \to \alpha, \gamma \to \alpha + \text{Fe}_3\text{C})$ on surface roughness. In this paper, the surface roughness *R*a(δ/γ) of peritectic According to the results of Guo et al. [\[20\]](#page-9-14), the surface roughness of peritectic steel was influenced steel was measured using the b-method.

3. Results and Discussion

3.1. Solidification Process of Steels during Cooling

Here, the solidification processes of three kinds of peritectic steels with different carbon content were observed using a CSLM, and the solidification processes were analyzed in combination with the evolution of the microstructure.

3.1.1. 0.10C% Hypo-Peritectic Steel

Figure [4](#page-4-0) shows the change in the steel sample's surface when S1 cooled from the liquid state to the solid phase. The big cooling rate during the early stage of solidification delayed the temperature of nucleation and transformation; thus, the steel sample at high temperature in the non-equilibrium state obtained a large degree of undercooling. When the temperature was lower than 1488.3 ◦C, the δ phase began to nucleate and grow gradually. The liquid contracted continuously due to cooling, and liquid hollows formed between the δ grains (the black region in Figure [4a](#page-4-0),b). The solidification process in the hollows could not be observed, as the reflected light from the hollows could not be reflected back. Therefore, the exact temperature at which the liquid phase of the steel disappeared could not be determined in this experiment. As shown in Figure [4b](#page-4-0),c, the surface of the δ grains remained smooth until the temperature decreased to 1328.5 ◦C, then the surface wrinkled. Shibata et al. [\[14\]](#page-9-8) and Dippenaar et al. [\[18\]](#page-9-12) also noticed this phenomenon when observing the $\delta \rightarrow \gamma$ transformation process through a CSLM in situ, and Guo et al. [\[20\]](#page-9-14) deemed the wrinkles to be the surface roughness due to the $\delta \rightarrow \gamma$ transformation. As the transition rate was too fast, only the change in the surface roughness of the steel sample before and after the transition was observed.

(b,c) before and after δ - γ transformation; (d) the wrinkles of low temperature phase transformation. **Figure 4.** Confocal scanning laser microscope (CSLM) results of the 0.10C% steel. (**a**) δ growth;

The δ→γ transformation temperature of the S1 steel sample ranged from 1328.5 °C to 1303.1 °C. When the temperature was below 1303.1 °C, wrinkles were no longer added the surface of the steel

sample until the temperature lowered to the range of 721–650 \degree C, which was when the wrinkles in the steel surface increased again. The appearance of the wrinkles in this temperature range is shown in Figure [4d](#page-4-0), which had directionality in a small range and could hardly separate the influence of eutectoid transformation and the transformation of austenite to proeutectoid ferrite on the surface roughness. Therefore, the change of surface roughness after 721 $°C$ was considered to be the result of the joint action of the austenite to proeutectoid ferrite transformation process and eutectoid transformation. After 650 \degree C, no change in the surface roughness of the steel sample was observed by the CSLM.

3.1.2. 0.14C% Hypo-Peritectic Steel

Figure [5](#page-5-0) shows the change of surface roughness during the solidification process of S2. It can be seen that the δ -ferrite nucleated from the liquid phase at 1464.2 °C. Similar to the solidification process of S1, the liquid formed hollows due to the shrinkage. The temperature range of the δ $\rightarrow \gamma$ transformation of S2 was 1334–1299.7 °C. Figure [5b](#page-5-0),c exhibits the contrast of the surface before and after the transformation, where surface wrinkles generated on the crystal surfaces. When the temperature was below 1299.7 °C, the surface of the steel sample no longer continued to grow wrinkles until the temperature dropped to the range of 720–640 °C, which was when the surface wrinkles increased again. The appearance of the wrinkles in this temperature range is shown in Figure [5d](#page-5-0), which had directionality in a small range. $\overline{}$ formation of the secondary is the contracted to grow we writing to the the temperature of the temperature of 720–640 μ

Figure [6](#page-6-0) shows the solidification process of S3, where the δ -ferrite nucleated from the liquid phase at 1461.7 °C. It was observed that the peritectic transition temperature of S3 was around 1303.1–1297.7 ℃. As shown in Figure [6c](#page-6-0), the steel surface became rough after the peritectic phase $\frac{1}{2}$ the surface roughness was definitely caused by the δ , the transformation transition, and the surface roughness was definitely caused by the $\delta \rightarrow \gamma$ transformation shrinkage as surface roughness *R*a(δ/γ). When the temperature dropped to the range of 713.5–642 °C, wrinkles appeared once again on the surface of S3, and these wrinkles were defined as the low temperature *Metals* **2018**, *8*, x 8 of 12 phase transformation surface roughness. Unlike the surface roughness $Ra(\delta/\gamma)$, the low temperature phase transformation surface roughness had a certain directionality in a small range.

(d) the wrinkles of low temperature phase transformation. **Figure 6.** CSLM results of the 0.16C% steel. (**a**) δ growth; (**b**,**c**) before and after δ–γ transformation;

3.2. Surface Roughness Ra(δ/γ) 3.2. Surface Roughness Ra(δ/γ)

During solidification process, the δ/γ phase transformation accompanied by the change of lattice $\frac{1}{2}$ in a difference in thermal expansion coefficient, causing stress concentration $\frac{1}{2}$ structure, resulting in a difference in thermal expansion coefficient, causing stress concentration and shrinkage on the surface [\[26](#page-9-18)[,27\]](#page-9-19). Figure [7](#page-7-0) is the surface measurement area of S1 as observed through a CSLM, where the low temperature phase transformation surface roughness had directionality, represented the transformation of austenite to prove the transformation ferrite, where under a cooling rate of \overline{r} as shown by the blue arrow in Figure [7.](#page-7-0) Liu et al. [\[28\]](#page-9-20) suggested that the low temperature wrinkling represented the transformation of austenite to proeutectoid ferrite, where under a cooling rate of roughoid ferrite first one in the gripped quotenite groin hour dem nucle $1 °C/s$, the proeutectoid ferrite first grew in the original austenite grain boundary nucleation and along the grain boundary. Therefore, the direction of the low temperature phase transformation surface roughness is dependent on the growth orientation of the proeutectoid ferrite. The two different results of the a-method and b-method are shown in Table [2.](#page-7-1) Surface roughness has a variety of parameters, and *R*a is widely used as it is a representative estimate of surface roughness, it is easily calculated, the equipment for it is affordable, and it can be expressed in the overall contour deviation from the centerline [\[29,](#page-10-0)[30\]](#page-10-1). For the a-method, the average value of *R*a was 39.5 µm, and after calculation by Equation (1) [\[20\]](#page-9-14), the value of the δ→γ transformation surface roughness *R*a(δ/γ) was 29.5 µm. Furthermore, the average value of the b-method was 32 μ m, which was similar to the *Ra(δ/γ)* value of 29.5 µm. Therefore, the surface roughness measurement line along the direction of the wrinkles avoided the influence of low-temperature phase transformation on surface roughness and measured the value of surface roughness $Ra(\delta/\gamma)$ directly.

$$

Table 2. The surface roughness parameters of different measurement methods. **Table 2.** The surface roughness parameters of different measurement methods.

can be experimented the surface roughness of metal to be positively proportional to be positively pro Figure [8a](#page-8-2) shows the relationship between the surface roughness value $Ra(\delta/\gamma)$ and the steel carbon content. Abe et al. [\[31\]](#page-10-2) considered the surface roughness of metal to be positively proportional to the strain and proposed in Equation (2) to describe the relationships between surface roughness and strain. Therefore, the value of surface roughness *R*a(δ/γ) represents the degree of peritectic transformation shrinkage. In this paper, the cooling rate of the peritectic steel during the initial solidification process was 20 °C/s, and the undercooling when the $\delta \rightarrow \gamma$ transformation occurred was about 180 °C (ΔT = 180 °C), according to the in situ observations. The maximum *R*a(δ/γ) value was found in the 0.10C% peritectic steel (*R*a (δ/γ) = 32 μm), the *Ra*(δ/γ) value of the 0.14C% peritectic steel $\frac{1}{2}$ and the $\frac{1}{2}(S(s))$ scales of the 0.166% positive to the calculated value of T and T and $\frac{1}{2}$ was 25 μm, and the *R*a(δ/γ) value of the 0.16C% peritectic steel was 17 μm. Therefore, as the carbon was in good the 0.16C% peritectic steel was 17 μm. Therefore, as the carbon content increased from 0.10C% to 0.16C%, the shrinkage degree of the $\delta \rightarrow \gamma$ transformation gradually decreased. As shown in Figure [8a](#page-8-2),b, the experimental results conformed to the calculated value of Jablonka et al. [\[11\]](#page-9-5). The carbon content dependence of the calculated thermal contraction was in good agreement with the measured surface roughness $Ra(\delta/\gamma)$. The study indicated that the transformation shrinkage degree of peritectic steel was proportional to the surface roughness of the shell under the large cooling rate, and the surface roughness could be used to characterize the degree of the peritectic δ $\rightarrow \gamma$ transformation shrinkage.
