Isolates were chosen based on their susceptibility to marbofloxacin, and those reported as FQ-resistant were screened for the presence of chromosomal mutations on DNA gyrase and Topoisomerase IV, and also for the presence of plasmid-mediated quinolone resistance (PMQR) genes in *E. coli*.

^a Methicillin resistance was confirmed by the presence of *mecA* gene. ^bWT: wild-type bacteria

^c susceptibility to marbofloxacin was assessed according to clinical breakpoints from CLSI guidelines VET01S [1]. Resistance was considered if MIC ≥ 4 µg/mL.

Table S2. Pharmacokinetic data (free concentration) obtained from preclinical studies in dogs following oral administration of marbofloxacin (2 mg/kg Schneider, *et al.* [2] or pradofloxacin (3 mg/kg Hauschild, *et al.* [3].

FQ	Dose (mg/kg)	Route	fC_{\max} ($\mu\text{g/mL}$)	T_{\max} (hours)	Clearance ($\text{L}\cdot\text{kg}^{-1}\cdot\text{h}^{-1}$)	$\text{AUC}_{0-24\text{h}}$ ($\mu\text{g}\cdot\text{h}\cdot\text{mL}^{-1}$)	$\text{AUC}_{0-\infty}$ ($\mu\text{g}\cdot\text{h}\cdot\text{mL}^{-1}$)	Protein binding (%)
Marbofloxacin	2	PO	1.25	25	0.1	14.55	19.96	9.1 (product monograph) 25 (Bregante, Bidgood and Papich)
Pradofloxacin	3	PO	1.19	2.33	0.244	10.75	12.27	36-37

C_{\max} : maximum serum drug concentration. T_{\max} : time necessary to achieve C_{\max} . Half-life: time at which the initial drug concentration is reduced by 50%; Clearance: amount of drug that is removed from the body per unit of time; AUC is the area under the concentration curve; Protein binding is the amount of drug bound to plasmatic proteins (data were obtained from separate sources, marbofloxacin (product monographs of Marbocyl® [4] and Zeniquin® [5] and pradofloxacin from Bregante, *et al.* [6].

E_{max} , maximal increase in killing rate in addition to K_{DEATH} , EC_{50_S1} : concentration required to achieve 50% of E_{max} for the dominant more susceptible population S1; gamma, Hill's coefficient; coefficient of variation (CV%) and confidence interval (CI) are represented in the Hessian matrix and obtained by simple run model. FOLD is a parameter that represents the potency ratio between the EC_{50S2} and EC_{50S1} .

Minimum inhibitory concentrations were estimated by the model and compared with experimentally measured MICs. Coefficient of variation (CV%) and confidence interval (CI) are represented in the Hessian matrix and obtained by simple run model.

Table S9. Critical PK/PD values ($fAUC_{PK_0-24h}/MIC$) that achieve 50% and 90% of the maximal antibacterial effect from the *in silico* model. Two representative isolates (susceptible and resistant) were chosen for each bacterial species (*S. pseudintermedius*, *S. aureus* and *E. coli*). Concentration is a unitless value which represents the average free plasma concentration required over 24 h to achieve 90% of the maximal efficacy.

Dose fractionation

Isolate	PRADOXIFLOXACIN				MARBOXIFLOXACIN			
	Experimental MIC (µg/mL)	$fAUC_{PK_0-24h}/MIC$ (h)		Average concentration (µg/mL) to achieve 90% of I_{max}	Experimental MIC (µg/mL)	$fAUC_{PK_0-24h}/MIC$ (h)		Average concentration (µg/mL) to achieve 90% of I_{max}
		50%	90%			50%	90%

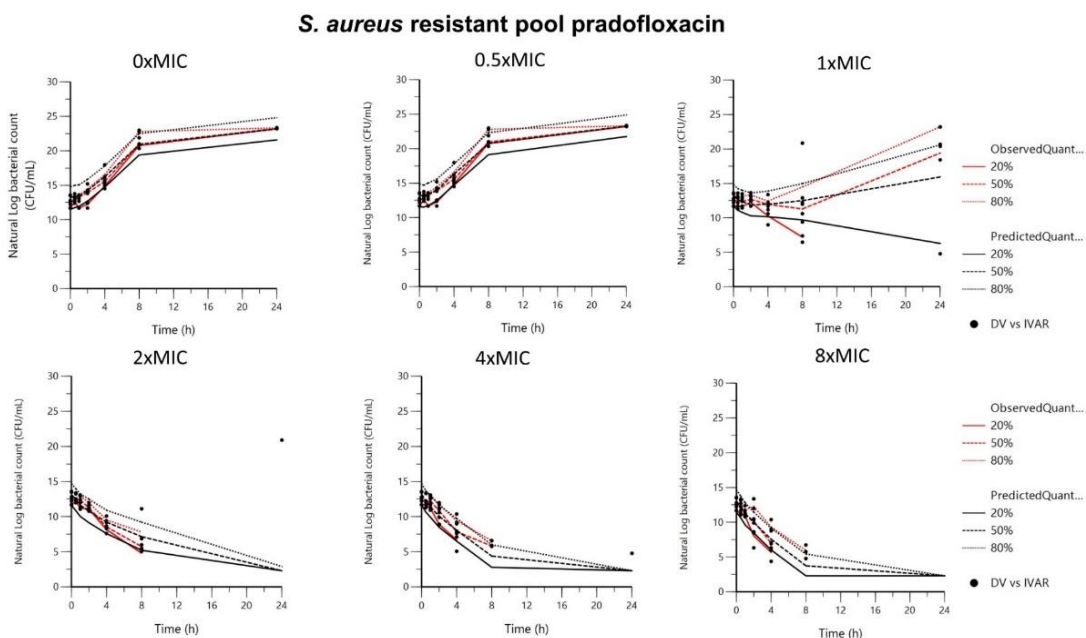

Figure S6. Visual predictive check (VPC) of pradofloxacin-resistant *S. aureus*. Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

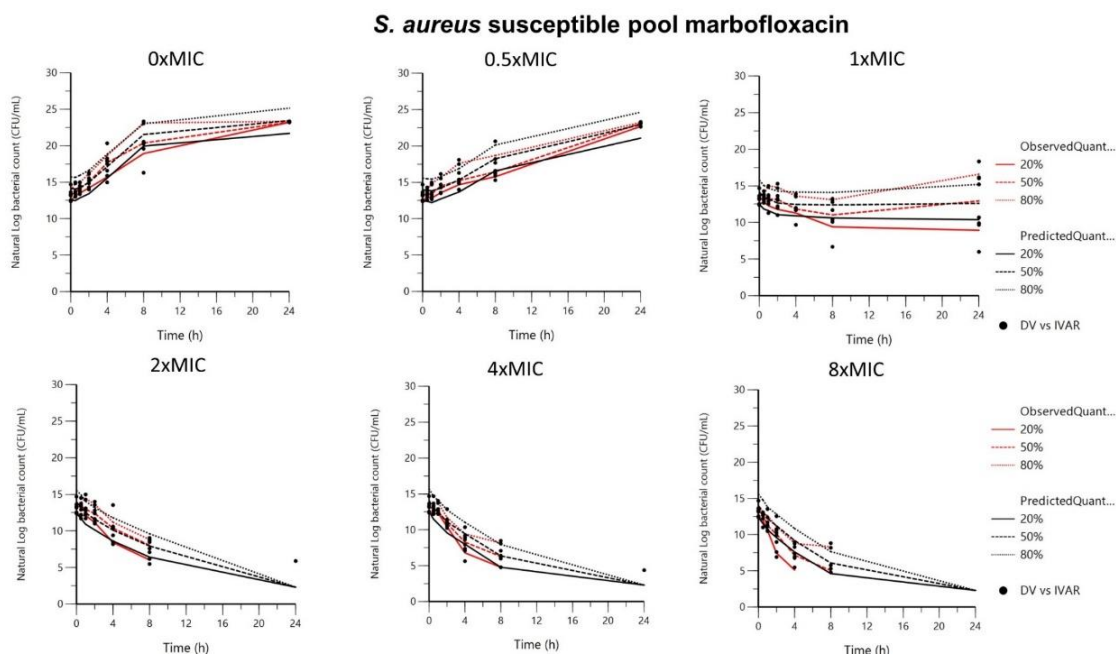

Figure S7. Visual predictive check (VPC) of marbofloxacin-susceptible *S. aureus*. Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

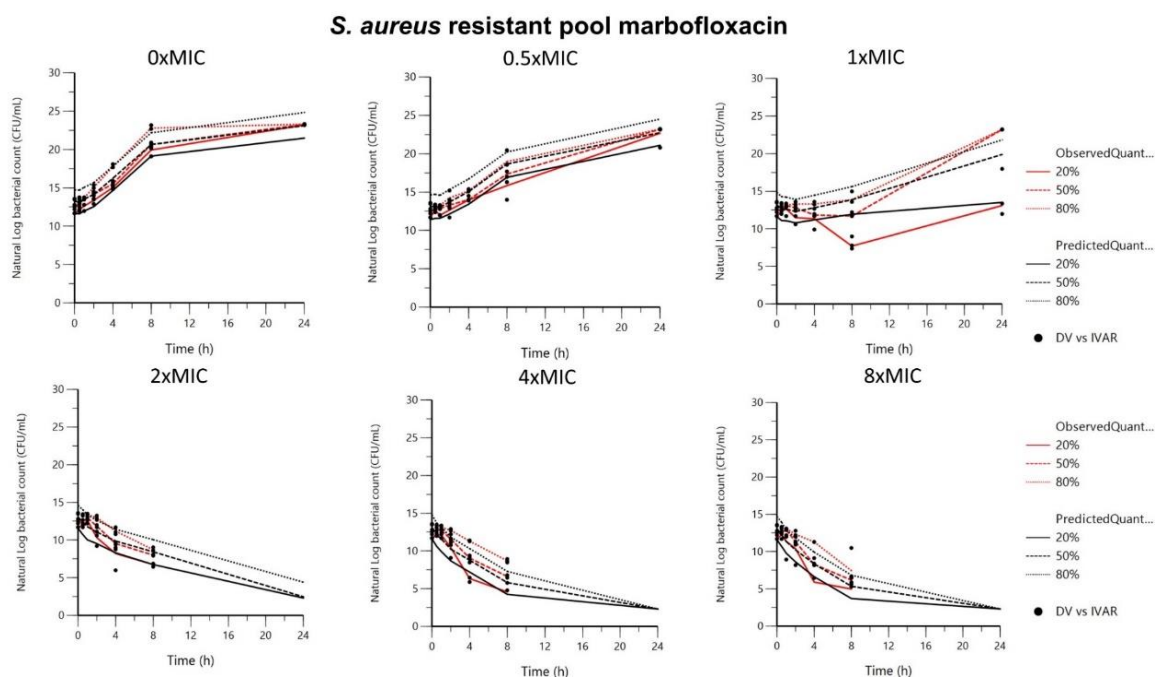

Figure S8. Visual predictive check (VPC) of marbofloxacin resistant *S. aureus*. Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

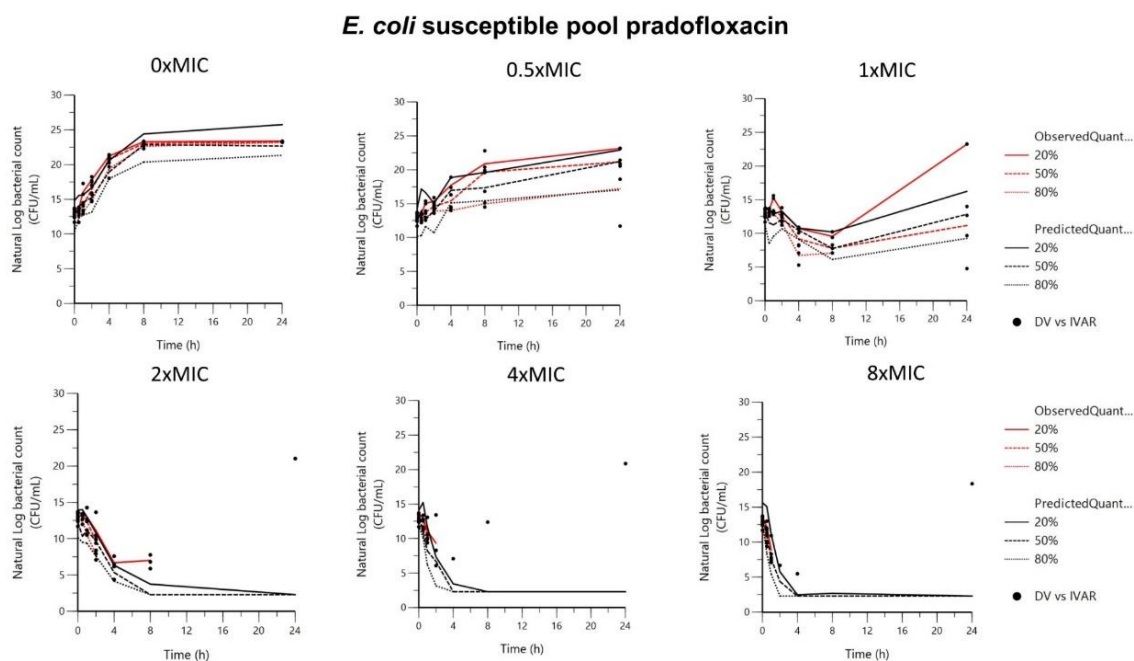

Figure S9. Visual predictive check (VPC) of pradofloxacin-susceptible *E. coli*. Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

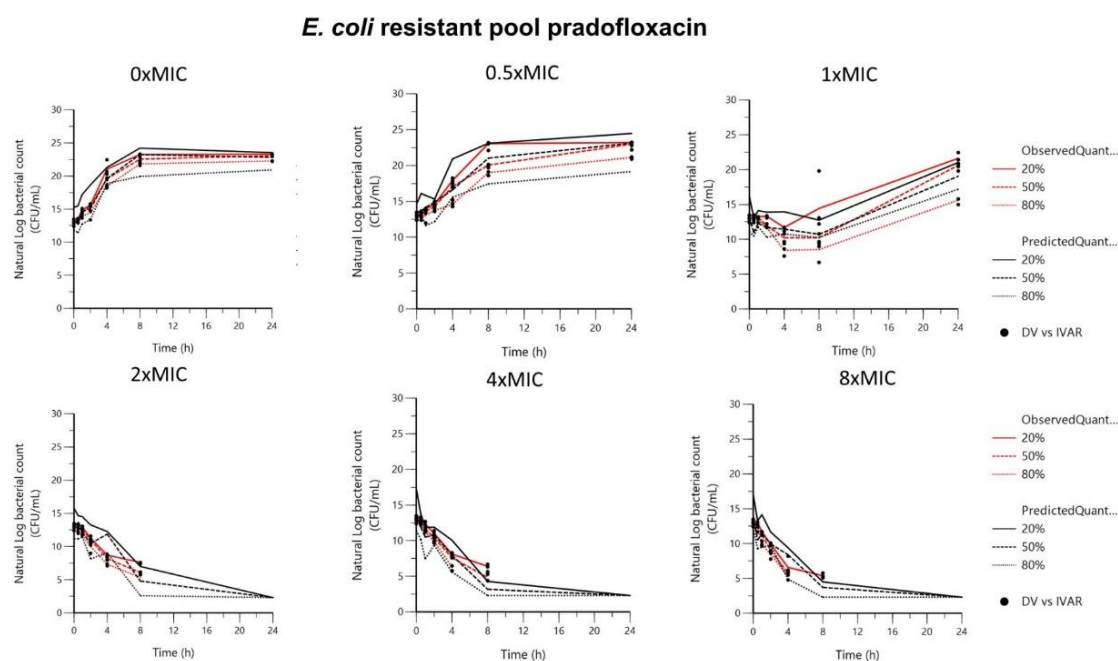

Figure S10. Visual predictive check (VPC) of pradofloxacin-resistant *E. coli*. Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

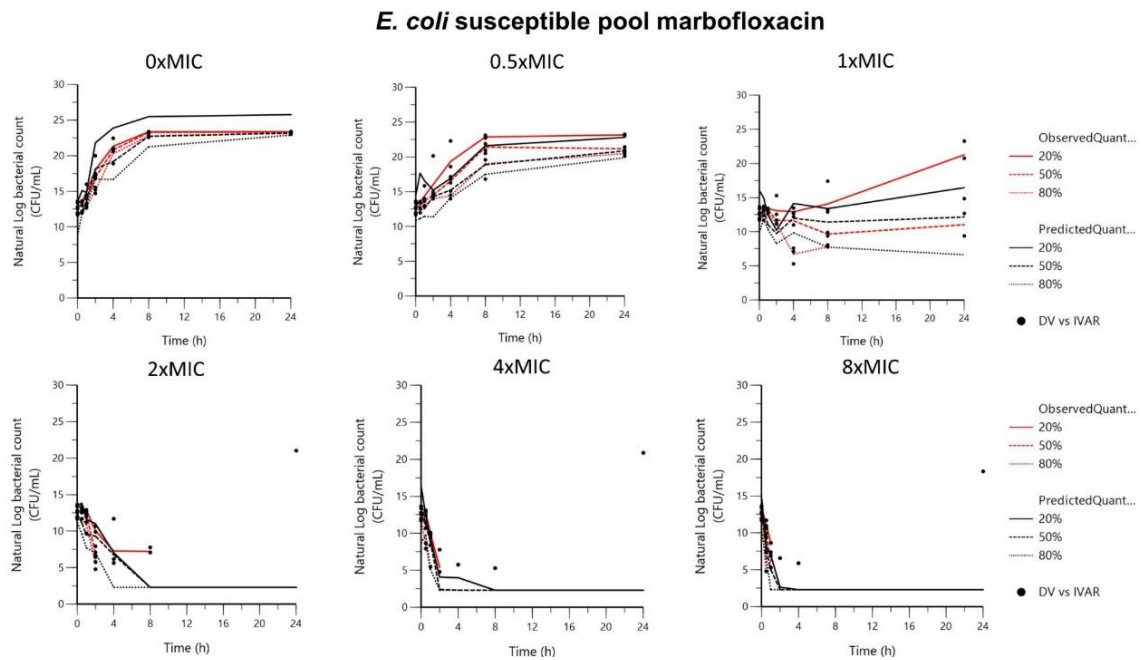

Figure S11. Visual predictive check (VPC) of marbofloxacin-susceptible *E. coli*.

Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

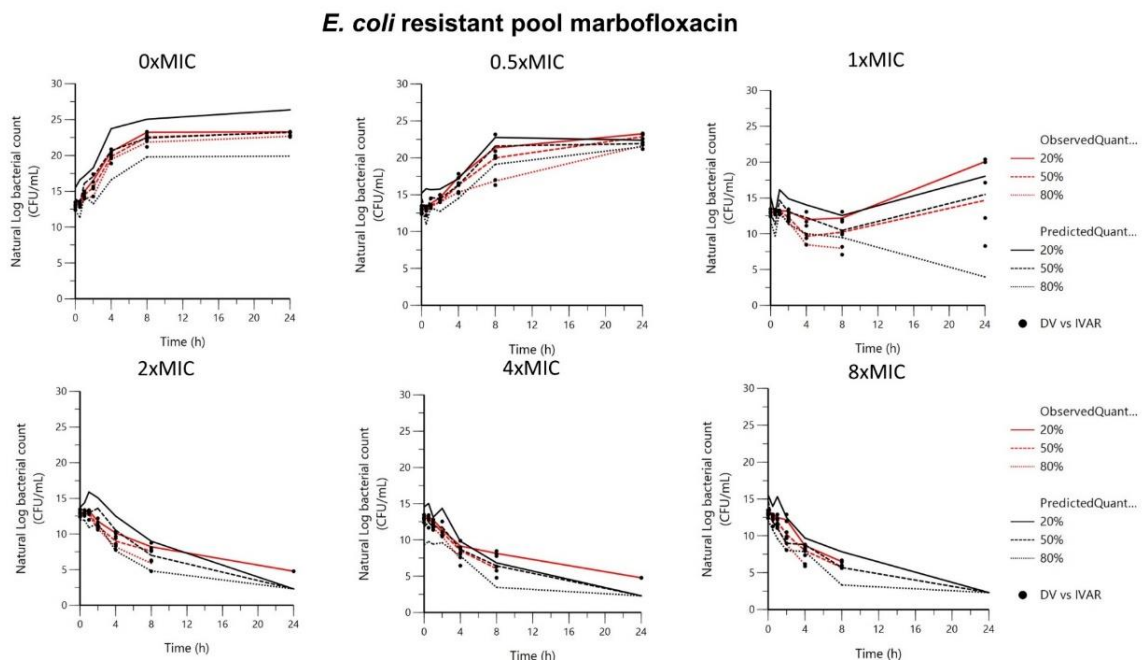

Figure S12. Visual predictive check (VPC) of marbofloxacin-resistant *E. coli*.

Each stratification for each observed quantiles (20, 50 and 80%, red lines) are superimposed with the predicted quantiles (20,50 and 80%, black lines). Black dots represent the observed data.

Figure S13. Predicted bacterial count (IPRED, expressed) versus observed bacterial count (DV) in 4 FQ-susceptible and 4 FQ-resistant *S. pseudintermedius*. Data are expressed as CFU/mL and are log normal transformed. Observed vs predicted values (black dots) should ideally be aligned to the unity line ($y=x$)

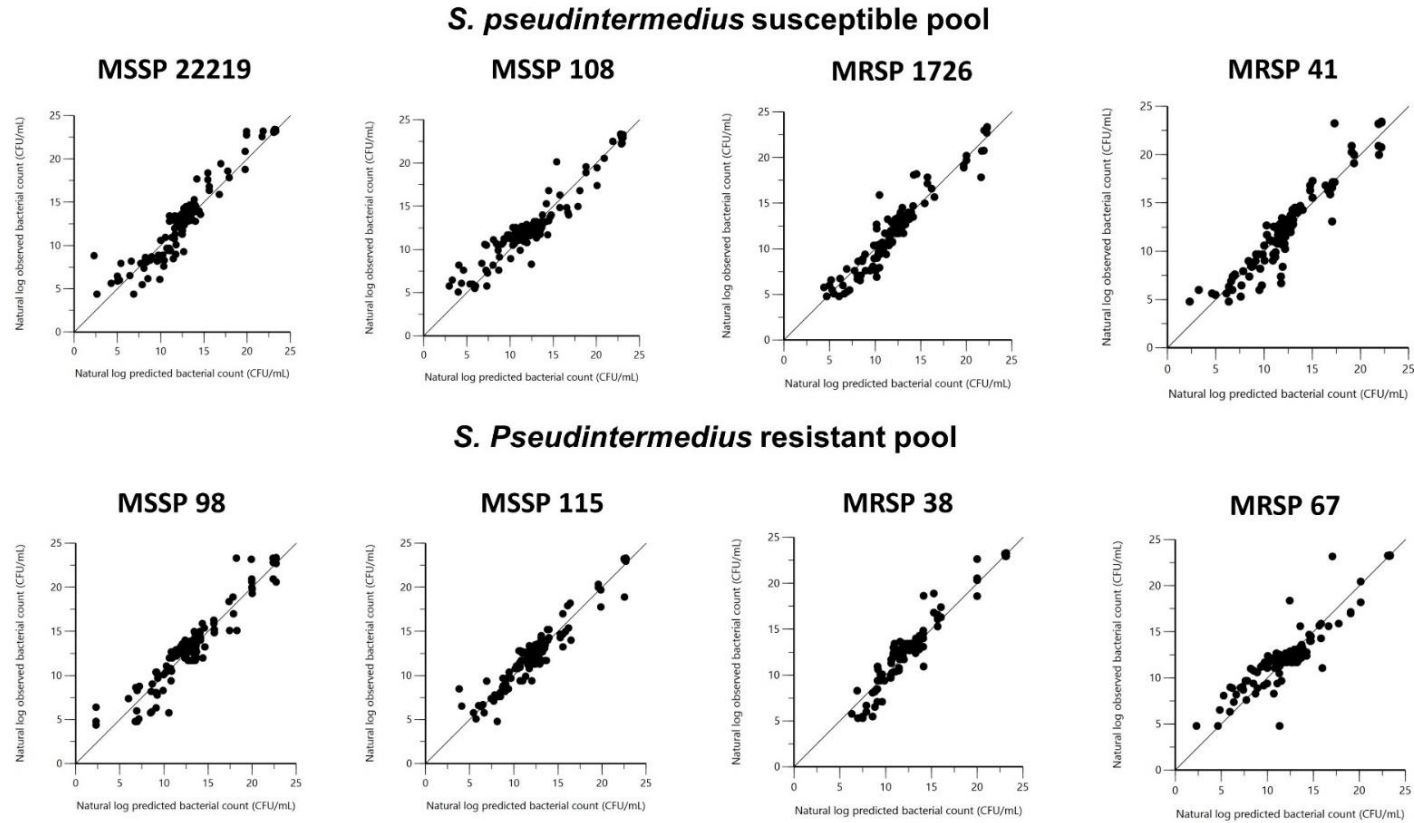

Figure S14. Predicted bacterial count (IPRED, expressed) versus observed bacterial count (DV) in 4 FQ-susceptible and 4 FQ-resistant *S. aureus*. Data are expressed as CFU/mL and are log normal transformed. Observed vs predicted values (black dots) should ideally be aligned to the unity line ($y=x$).

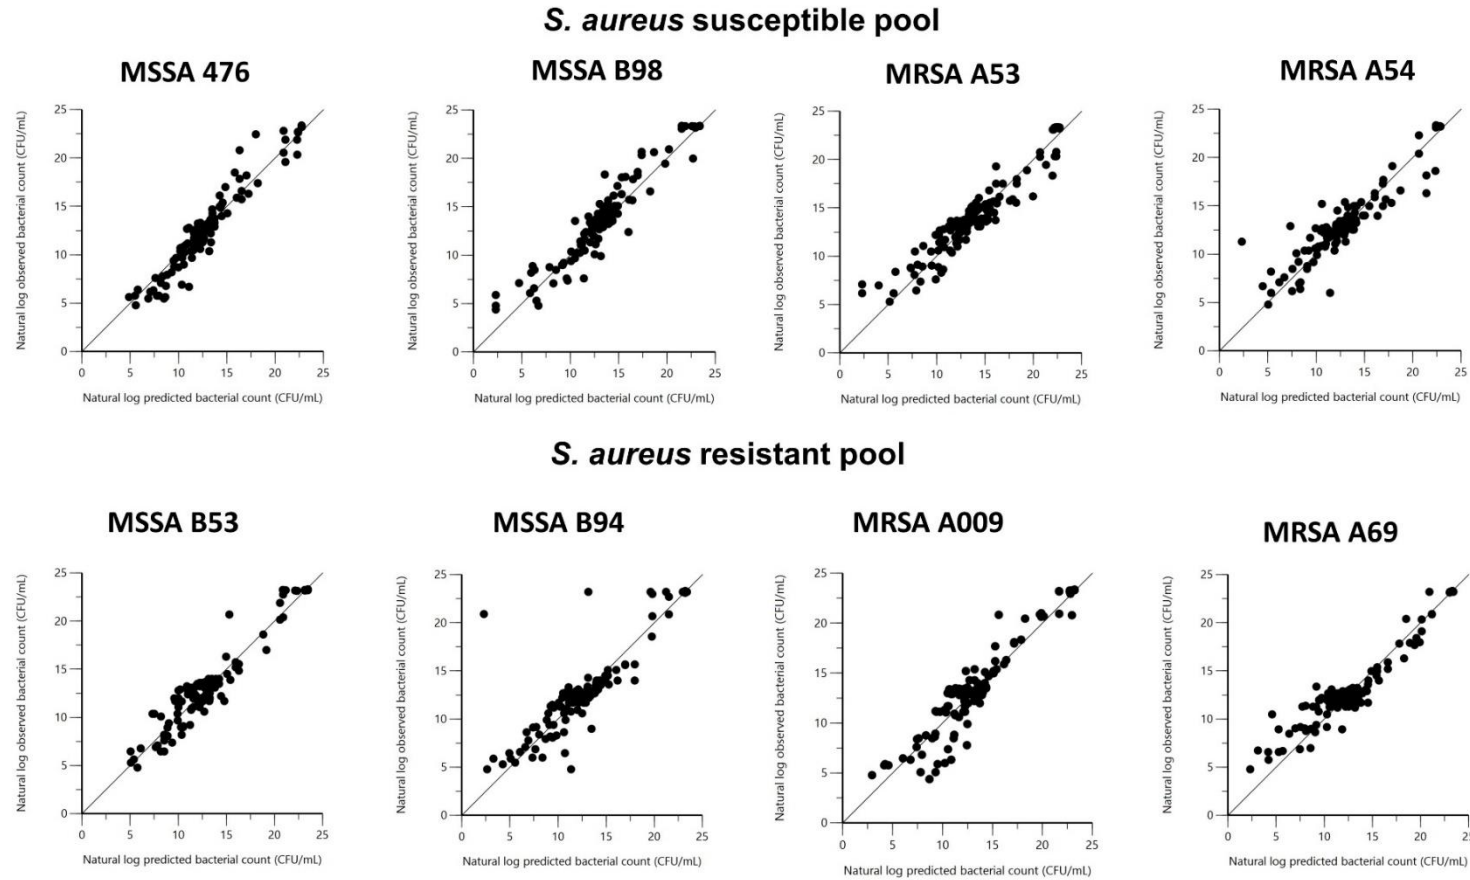

Figure S15. Predicted bacterial count (IPRED, expressed) versus observed bacterial count (DV) in 4 FQ-susceptible and 4 FQ-resistant *E. coli*. Data are expressed as CFU/mL and are log normal transformed. Observed vs predicted values (black dots) should ideally be aligned to the unity line ($y=x$).

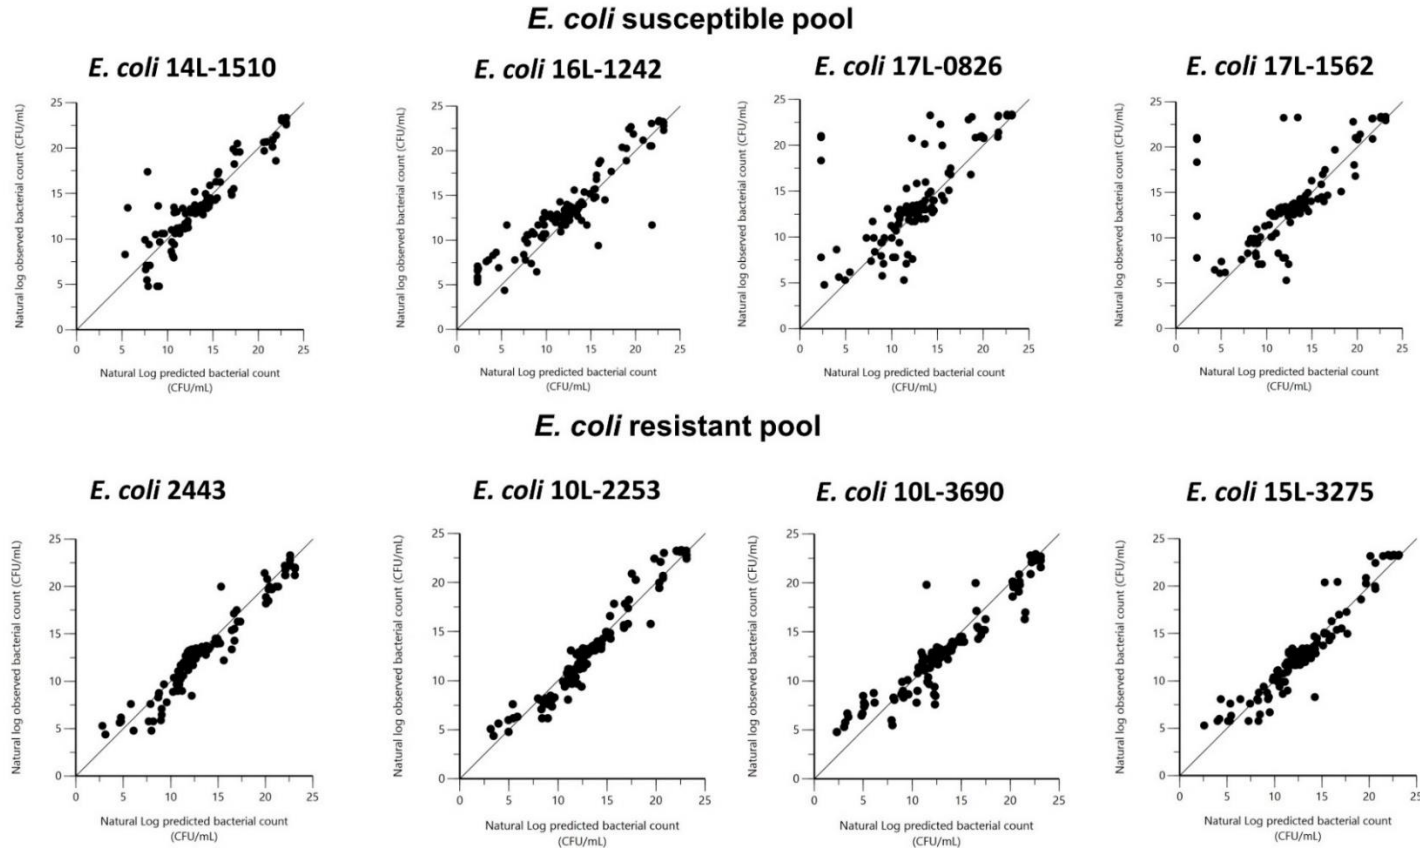

Figure S16. Plot of CWRES (conditional weighted residuals) and IWRES (individual weighted residuals) vs Predicted bacterial count (PRED) for the three bacterial species used in the study. CWRES/IWRES represent the goodness of statistical fit and values should be concentrated between $y = -2$ and $y = +2$. Values that are above 3 or below -3 may indicate a lack of fit.

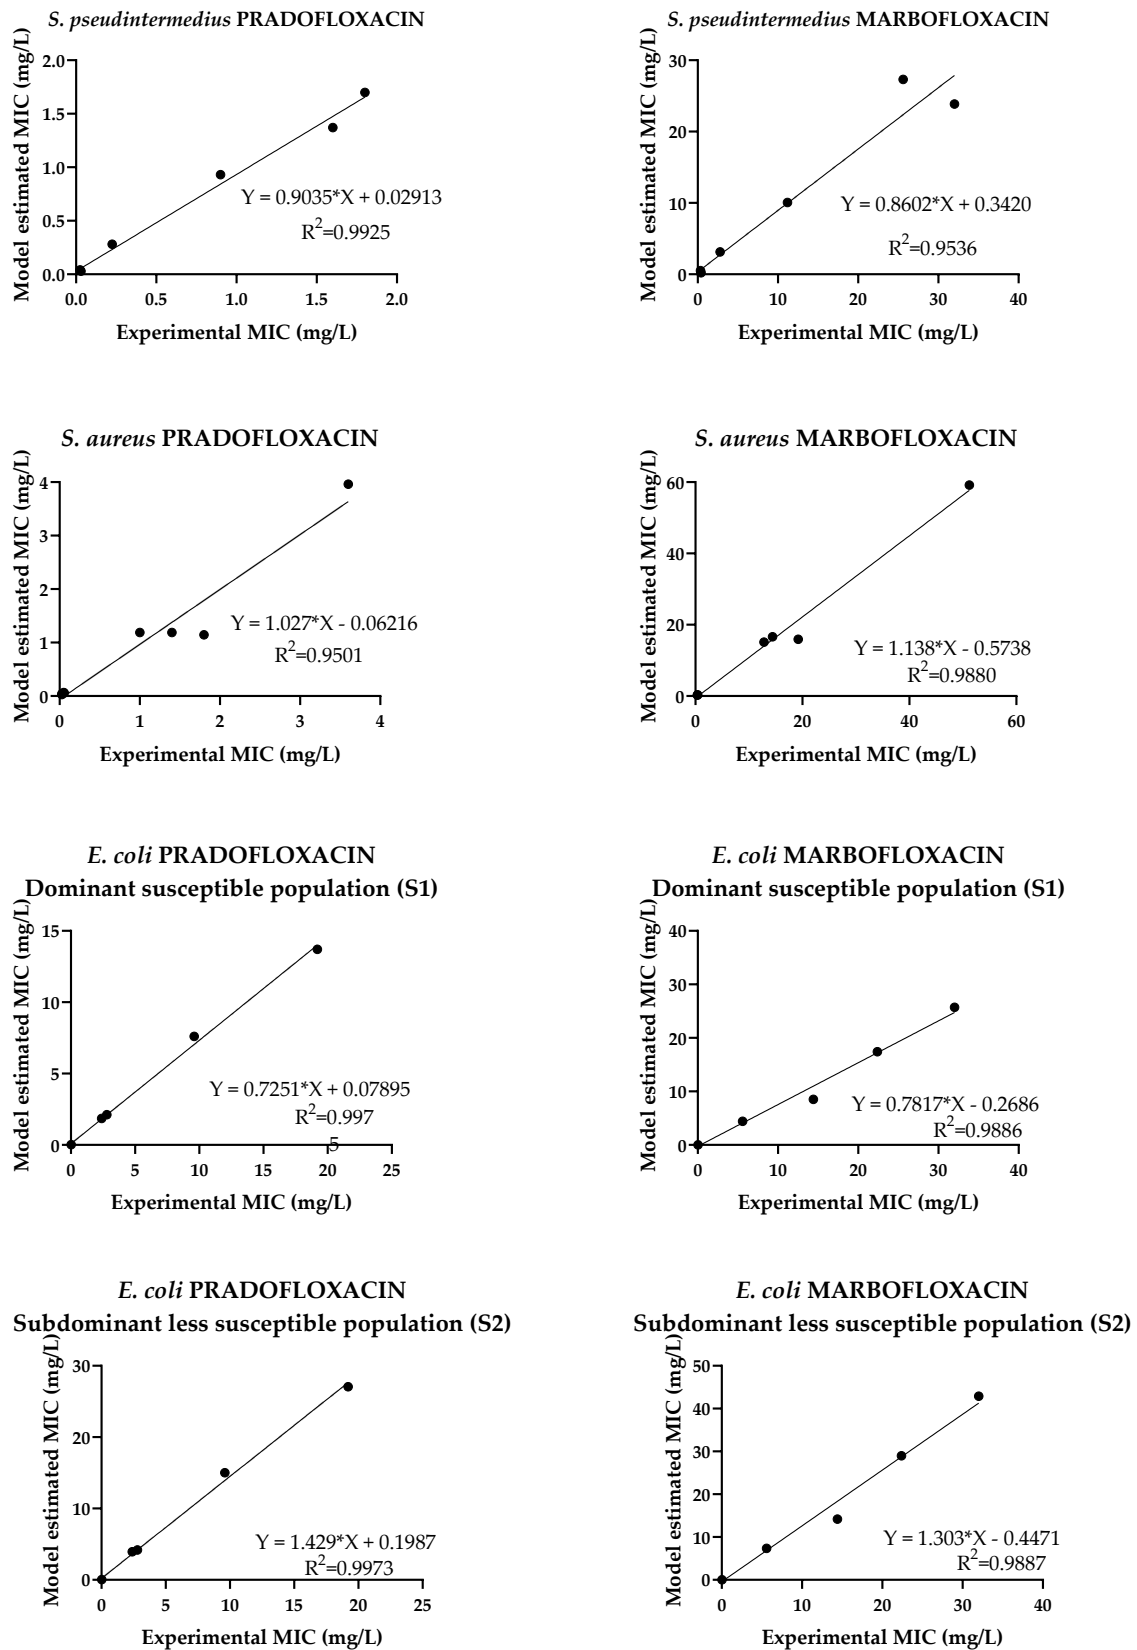

Figure S17. Simple linear regression between experimental (x axis) and model-estimated MICs in *S. pseudintermedius*, *S. aureus* and *E. coli* collected from canine skin infection cases.

Text S1 Mathematical modelling

Bacterial growth model

Compartment “S” has a growth rate constant, (k_{growth} , expressed in h^{-1}). To capture the progressive increase of K_{growth} from 0 to a maximal value ($k_{\text{growthmax}}$), k_{growth} was adjusted based on the following equation:

$$K_{\text{growth}} = K_{\text{growthmax}} \times (1 - e^{-(\alpha \times \text{time})})$$

Where α , expressed in h^{-1} , represents the progressive increase in k_{growth} that reaches a maximum rate, expressed as $k_{\text{growthmax}}$. The corresponding mean generation corresponds to $\ln 2 / k_{\text{growth}}$ (expressed in h).

The maximal bacterial carrying capacity of the system (populations S and P) is referred to as B_{max} (observed plateau in bacterial density). During bacterial growth, the semi-mechanistic model predicts that a proportion of the bacteria from the susceptible compartment are transferred to the P compartment at a constant rate called k_{SP} . No growth is assumed in the P compartment.

Moreover, both compartments share the same death rate constant (k_{death} , expressed in h^{-1}). To maintain good identifiability of model parameters, the value of this parameter has traditionally been fixed to 0.179 h^{-1} by previous authors [7-9] and we allocated this value to k_{death} in our models.

Drug effect model

The model also included drug effect, considered as additional to K_{death} . It is expressed as k_{drug} (unit h^{-1}) through the Hill's equation:

$$K_{\text{drug}} = \frac{(E_{\text{max}} \times C^{\gamma})}{(EC_{50}^{\gamma} + C^{\gamma})}$$

where, E_{max} is the maximum killing rate effect (h^{-1}), EC_{50} (mg/L) is the concentration of the drug able to reach 50% of E_{max} and γ (scalar), the Hill's coefficient. These parameters represent efficacy, potency and sensitivity of the tested antibiotics, respectively. To account for the differences in measured MIC (related to drug potency), we estimated a separate value of EC_{50} for each isolate.

Mathematical modelling

The following differential equations describe the change in number of viable bacteria over time in the S and P compartments:

$$\frac{dS}{dt} = k_{\text{growth}} \times S - (K_{\text{death}} + K_{\text{drug}}) \times S - K_{\text{SP}} \times S$$

$$\frac{dP}{dt} = K_{\text{SP}} \times S - K_{\text{death}} \times P$$

The constant of transfer between S and P is described by the following equation:

$$K_{SP} = \frac{(k_{\text{growth}} - K_{\text{death}})}{B_{\text{max}}} \times (S + P)$$

All data obtained in a TKC were simultaneously analysed with a Non-linear Mixed Effect Model (NLMEM).

As differences in B_{max} were observed between isolates for the staphylococci (only), a random component was included in the model with a Between Isolate Variability (BIV), which was modelled using an exponential model of the form:

$$\theta_{B_{\text{max}},i} = \theta_{\text{tv},B_{\text{max}}} \times \text{Exp}(\eta_i)$$

With θ_i is the value of theta (here B_{max}) in the i^{th} isolate, $\theta_{\text{tv},B_{\text{max}}}$ is the typical population value of this theta and η_i , the deviation (noted eta) associated to the i^{th} isolate from the corresponding theta population value.

An exponential error model was selected to model residual variability to account for the wide range of possible bacterial counts according to the following equation:

$$Y_{ij} = \hat{Y}_{ij} \times e^{\varepsilon_{ij}}$$

\hat{Y}_{ij} represents the j^{th} response (expressed in CFU/mL), which is calculated in the i^{th} curve with no initial log transformation of raw data, whereas ε_{ij} represents the common errors terms with a mean of 0 and a variance of σ^2 . If an exponential model is specified, and if there is only one error model as for our analysis, the predictions and observations were automatically log-transformed by the software and are fit in that space. This is because the error model becomes additive in log-space, which allows for higher performance and accuracy. This affects all the plots results and residuals because they are in log-space.

Precision of parameter estimates was estimated by computing standard error (SE) using the Hessian method. When the engine was unable to return these values, precision of parameters and their confidence intervals were estimated by a bootstrap method ($n = 30$ samples).

Model fitting and diagnostic plots

Candidate models were assessed by goodness-of-fit plots (PRED (population prediction) and IPRED (individual prediction) versus dependent variable (i.e. time), and by inspection of residuals CWRES (conditional weighted residuals).

Moreover, Visual Predictive Check (VPC) allowed graphical comparisons of the 20th, 50th (median) and 80th percentiles between model-predicted intervals and observed data, VPC were derived from $n=200$ simulated data sets, stratified by drug and initial bacterial pool (marbofloxacin-susceptible or resistant isolate).

Secondary parameters

MIC and MBC were estimated through the following equations, introduced by Mouton and Vink [10]:

$$MIC = EC_{50} \times \left(\frac{K_{growth} - 0.221}{E_{max} - (K_{growth} - 0.221)} \right)^{\frac{1}{\gamma}}$$

The constant 0.221 was obtained from the following equation:

$$\frac{1}{Time\ of\ measurement(24h)} \times LN \left(\frac{N(t)}{N(0)} \right) = 0.221$$

Where N(t) represented the inoculum size at time 18h, which was set at 10⁸ CFU/mL (bacterial density associated with visible growth) and N(0) the initial inoculum of 5x10⁵ CFU/mL.

Pre-existing heterogenous population model

The initial model proposed by Nielsen and Friberg [11] did not capture the regrowth of bacteria observed at 1XMIC. We therefore hypothesised that pre-existing subdominant less susceptible bacteria were present within the total population *E. coli.*, as described by Campion et al. [12]. The ratio between subdominant less susceptible bacteria and total bacteria population has been shown from growth curves to be approximately 10⁻⁸ to 10⁻⁹ [13]. The initial susceptible population (starting inoculum) consisted of two subpopulations representing a heterogenous bacterial population with a proportion (F1) of bacteria being a highly susceptible dominant population (S1) and the remaining sub-dominant population (S2) having a lower susceptibility. F1 was estimated by the model. Apportioning of the starting inoculum (SLoad) to each of the initial sub-populations is defined by the following equations:

Proportion of initial inoculum that is apportioned to subpopulation S1.

$$S1 = SLoad \times F_1$$

Proportion of initial inoculum that is apportioned to subpopulation S2.

$$S2 = SLoad \times (1 - F_1)$$

A proportion of the susceptible population (S1 and S2) is irreversibly transferred to a non-susceptible, non-growing population at a rate constant (K_{SP}). Both S1 and S2 subpopulations were assumed to have a similar growth constant (K_{growth}) and natural death rate (K_{death}). Drug effect K_{drugS1} and K_{drugS2} were described by two separate E_{max} sigmoid models, including respectively E_{maxS1}, γ_{S1} and EC_{50S1} and E_{maxS2}, γ_{S2} and EC_{50S2}. The potency ratio between EC_{50S2} and EC_{50S1} was estimated by the parameter "FOLD", whose drug-specific values were shared between all isolates.

$$EC_{50_S2} = FOLD \times EC_{50_S1}$$
