**Abstract:** A few recent publications on interrupted time series analysis only conduct preintervention modelling and use it to illustrate postintervention deviation without quantifying the amount lost during the intervention period. Thus, this study aims to illustrate how to estimate and quantify the actual amounts (in South African Rands—ZAR) that the negative impact of the intervention effects of the COVID-19 pandemic had on the South African total monthly wholesale and retail sales using the seasonal autoregressive integrated moving average (SARIMA) with exogenous components (SARIMAX) model. In addition, the SARIMAX model is supplemented with three approaches for interrupted time series fitting (also known as a pulse function covariate vector), which are: (i) trial and error, (ii) quotient of fitted values and actual values, and (iii) a constant value of 1 throughout the intervention period. Model selection and adequacy metrics indicate that fitting a pulse function with a trial-and-error approach produces estimates with the minimum errors on both datasets, so a more accurate loss in revenue in the economy can be approximated. Consequently, using the latter method, the pandemic had an immediate, severe negative impact on wholesale trade sales, lasting for 15 months (from March 2020 to May 2021) and resulted in a loss of ZAR 302,339 million in the economy. Moreover, the retail sales were also negatively affected, but for 8 months (from March 2020 to October 2020), with a 1-month lag or delay, suggesting the series felt the negative effects of the pandemic one month into the intervention period and resulted in a loss of ZAR 87,836 million in the economy.

**Keywords:** wholesale trade sales; retail sales; COVID-19 intervention; SARIMAX; Box–Jenkins methodology

## **1. Introduction**

Intervention analysis provides a roadmap to modelling and estimating the intervention effect on a time series under study. In intervention analysis, the assumption is that the intervention affects the data-generating process by changing the mean function and trend of the underlying series [\(Cryer and Chan](#page-18-0) [2008\)](#page-18-0). In general, interventions differ in magnitude and type. Some are natural (such as tsunamis and earthquakes), some are human-made (such as the 9/11 attack), and some have unknown causes, such as the COVID-19 pandemic [\(Bogoch et al.](#page-18-1) [2020;](#page-18-1) [Wu et al.](#page-19-0) [2020\)](#page-19-0). Since the onset of the COVID-19 pandemic, many researchers have conducted interrupted time series (ITS) studies to assess the impact of the pandemic throughout various fields. Most researchers used the naïve ordinary least squares segmented regression model to estimate and quantify the pandemic effects [\(McIntosh et al.](#page-18-2) [2021;](#page-18-2) [Zhong et al.](#page-19-1) [2022;](#page-19-1) [Yoshioka et al.](#page-19-2) [2022\)](#page-19-2). Although segmented regression is a common approach, it is not always adequate, particularly when the data have seasonality and autocorrelation [\(Schaffer et al.](#page-19-3) [2021\)](#page-19-3).

The Box–Jenkins autoregressive integrated moving average (ARIMA) models are an alternative approach to accommodate seasonality, autocorrelation and other potential

confounding effects [\(Pridemore et al.](#page-19-4) [2014\)](#page-19-4). Unlike in segmented regression, there is no need to include time and seasonal dummy variables in the ARIMA model, as the model can accommodate stochastic seasonality in the data. Stated differently, the first differencing is to remove a trend, and a seasonal difference is to remove the seasonality component so that the series can be transformed from nonstationarity to stationarity. The basic assumption of ARIMA modelling is that the data-generating process of the underlying time series does not change over time [\(Montgomery et al.](#page-18-3) [2015\)](#page-18-3). However, in real-world applications, a time series may be subjected to interruptions, which affect the modelling and forecasting performance of the basic ARIMA models. As a result, [Box and Tiao](#page-18-4) [\(1975\)](#page-18-4) developed the autoregressive integrated moving average with exogenous components (ARIMAX) to incorporate these interventions into the series. The beneficial property of the ARIMAX model is that when conditions of the data-generating process of the underlying series are interrupted, the ARIMAX models are flexible and can be modified by using transfer functions to accommodate these changes [\(Inyang et al.](#page-18-5) [2023\)](#page-18-5).

Transfer functions (or impact variables) provide a functional form of the characterised relationship between the intervention and the series under study. They reconstruct the relationship between the step, pulse, and time series to model more complex intervention impacts, including gradual level shifts, a pulse with gradual decay, and lagged effects [\(Box](#page-18-6) [et al.](#page-18-6) [2015\)](#page-18-6). The pulse and step functions are the two general types of transfer functions [\(Inyang et al.](#page-18-5) [2023\)](#page-18-5). A step change is an abrupt, long-term change where the series level is moved either up or down by a particular value shortly after the intervention. A pulse is an abrupt, noticeable temporary change on one or more observations instantaneously after the intervention [\(Aliffia et al.](#page-18-7) [2024\)](#page-18-7).

According to [Bernal et al.](#page-18-8) [\(2017\)](#page-18-8), it is important to hypothesise the probable shape of the resulting impact before conducting the intervention analysis. This can be done using the response variable's pre-existing scientific knowledge and literature. Some intervention impacts are best represented by combining the step and pulse functions, and the resulting impact model can take different shapes and forms. A variety of impact models are found in [\(Montgomery et al.](#page-18-3) [2015;](#page-18-3) [Bernal et al.](#page-18-8) [2017,](#page-18-8) [2018;](#page-18-9) and [Bottomley et al.](#page-18-10) [2019\)](#page-18-10). In ITS analysis, ARIMA produces forecasts of the underlying series in the absence of the intervention, referred to as the "counterfactual series", which are used to evaluate how the actual values deviate from these forecasts in the intervention period [\(Bernal et al.](#page-18-8) [2017;](#page-18-8) [Bartholomew et al.](#page-18-11) [2023\)](#page-18-11). In the counterfactual scenario, the expected trend of the series remains unchanged. Therefore, the counterfactual series serves as a basis to compare the pattern of the interrupted series with how it would have unfolded had the intervention not occurred [\(Bartholomew et al.](#page-18-11) [2023\)](#page-18-11).

In South Africa, the wholesale and retail sectors collectively contribute around 15% to the Gross Domestic Product (GDP), constituting approximately 22% of the country's labour force [\(Sewell et al.](#page-19-5) [2016;](#page-19-5) [Mamaro and Mabandla](#page-18-12) [2022\)](#page-18-12). In particular, the retail sector is comprised of 87% small enterprises, 9.5% medium enterprises, and 4.5% large enterprises [\(Sewell et al.](#page-19-5) [2016\)](#page-19-5). As a result of the strict COVID-19 measures, small retail enterprises were the most severely affected in the sector [\(Arndt et al.](#page-18-13) [2020\)](#page-18-13). Large retail firms were no exception; for instance, the analysis of financial reports of twenty-two Johannesburg Stock Exchange (JSE)-listed South African retail firms showed that the COVID-19 pandemic had a statistically significant negative impact on the financial performance of these firms [\(Mamaro and Mabandla](#page-18-12) [2022\)](#page-18-12). As shown in [Chitiga-Mabugu et al.](#page-18-14) [\(2021\)](#page-18-14), both the wholesale and retail sectors were among many other sectors of the South African economy that were severely affected by the COVID-19 pandemic. Thus, the COVID-19 pandemic had a negative impact (during the intervention period) on the employment level, job creation capability, and profitability of firms in these sectors, which had a direct detrimental effect on the overall South African economy. This highlights the importance of quantifying the approximate losses in the wholesale and retail sectors due to the COVID-19 pandemic. It is worth mentioning that there are other studies that explore tests of policy ineffectiveness when the predicted values of the variable of interest are computed using the reduced form or final form policy response equations [\(Pesaran and Smith](#page-18-15) [2016\)](#page-18-15). Although the objectives of [Pesaran and Smith](#page-18-15) [\(2016\)](#page-18-15) and this study are aligned, which is to estimate the impact of the intervention or policy change on the target variable, the scope and objective of this study are different.

There is almost no research on the application of the ITS ARIMAX model in the context of the wholesale and retail sectors in South Africa and the rest of the world. However, similar research has been conducted in the past in other sectors to assess intervention effects with properties like COVID-19. For instance, in the health sciences, [Zhou et al.](#page-19-6) [\(2023\)](#page-19-6) used the ITS ARIMA approach to analyse the impact of the COVID-19 pandemic on the incidence rate of notifiable communicable diseases in China. ARIMA model with a change in slope that occurs immediately after the intervention was fitted to the data, and the results revealed a significant short-term decrease in the incidence rates of respiratory and enteric infectious diseases. Additionally, a short-term drop in the incidence rates of blood-borne and sexually transmitted infectious diseases with a step change was observed, which was likely to recover to the previous levels in the long term. There was no significant change in the incidence rate of natural focus diseases or arboviral diseases before and after the epidemic. In the oil industry, [Aliffia et al.](#page-18-7) [\(2024\)](#page-18-7) conducted a single-point intervention analysis with a pulse function to quantify the effect of the Russia–Ukraine conflict on the weekly price of crude oil. Among the models considered, ARIMA with a pulse function at the intervention point best fits the intervention series. The intervention parameters were estimated using the cross-correlation plot. The 12-week forecasts had relatively low model adequacy values (MAPE =  $2.89\%$  and MSE = 10.27). A study by [Inyang et al.](#page-18-5) [\(2023\)](#page-18-5) investigated the impact of the Declaration of Cooperation (DoC) by the Organisation of Petroleum Exporting Countries (OPEC) on monthly crude oil prices between January 1998 and December 2021. The Declaration of Cooperation had a statistically significant abrupt permanent increment of 33.72% to the price of crude oil immediately after it was introduced.

[Lam et al.](#page-18-16) [\(2009\)](#page-18-16) used an ARIMA model with a permanent step change to compute more precise and reliable estimates of the intervention effects and the asymptotic change observed in the business process reengineering simulation results from the activity model analysis. [Bartholomew et al.](#page-18-11) [\(2023\)](#page-18-11) investigated the effect of COVID-19 vaccinations on the daily COVID-19 cases in Nigeria using the naïve ordinary least squares linear regression model and the ITS ARIMA model. Five structural breaks were identified in the series, and the two models were fitted. Model selection metrics (AIC, BIC, and log-likelihood) showed that the naïve OLS regression model did not fit the data well and favoured the first differenced ITS ARIMA model with exogenous components. The intervention coefficient was negative, indicating that Nigeria's daily cases remained high after the vaccine rollout.

In the legislature, [Chamlin](#page-18-17) [\(2017\)](#page-18-17) used ITS ARIMA with zero-order transfer functions to assess and model the impact of New Jersey's blood and alcohol legislation on monthly total and separate mortalities of drivers and passengers from vehicle crashes. The results highlighted that the implementation of the blood and alcohol legislature had no significant effect on the number of deaths across all three outcome measures but proved to reduce vehicle crash fatalities by a rate of three passengers per month. In a similar study, [Humphreys](#page-18-18) [et al.](#page-18-18) [\(2013\)](#page-18-18) studied the immediate and delayed impacts of removing regulatory trading hours restrictions on alcohol sales on the weekly police cases of violence in England and Wales. The analysis reported a gradual and permanent shift (step change) of violence between 3 a.m. and 6 a.m. by a first-order transfer function with an initial increase of 27.5% at the start of the intervention. It increased to 36% towards the end of the study period. [Pridemore et al.](#page-19-4) [\(2014\)](#page-19-4) assessed the effect of the implementation of the 2006 alcohol policy on gender-specific monthly alcohol-related fatalities of the Russian population aged 15 years and above. The intervention effect was modelled using a first-order gradual change ARIMAX intervention model. The study results showed that the introduction of the alcohol policy reduced the annual alcohol poisoning fatalities of approximately 6700 males as well as 760 male and 770 female liver cirrhosis fatalities. Had the policy not been introduced,

male alcohol poisoning fatalities, female alcoholic liver cirrhosis, and male liver cirrhosis fatalities were estimated to have increased by 35%, 9%, and 15%, respectively.

In the South African context, studies using the Box–Jenkins methodology to independently investigate the long-term impact of the Global Financial Crisis (GFC) and COVID-19 pandemic on manufacturing, new car sales and the arrival of tourists were conducted [\(Makoni and Chikobvu](#page-18-19) [2023a,](#page-18-19) [2023b,](#page-18-20) [2023c;](#page-18-21) [Chipumuro et al.](#page-18-22) [2024;](#page-18-22) [Chikobvu and Makoni](#page-18-23) [2024\)](#page-18-23). Similarly, [Masena and Shongwe](#page-18-24) [\(2024a,](#page-18-24) [2024b\)](#page-18-25) used the Box–Jenkins methodology with SARIMA with exogenous component (SARIMAX) to illustrate the effect of the COVID-19 pandemic on wholesale and retail sales in South Africa. Although these studies [\(Makoni](#page-18-19) [and Chikobvu](#page-18-19) [2023a,](#page-18-19) [2023b,](#page-18-20) [2023c;](#page-18-21) [Chipumuro et al.](#page-18-22) [2024;](#page-18-22) [Chikobvu and Makoni](#page-18-23) [2024;](#page-18-23) [Masena and Shongwe](#page-18-24) [2024a,](#page-18-24) [2024b\)](#page-18-25) aimed to assess and quantify the intervention effect, there was no intervention analysis nor year-to-year comparisons evaluated to estimate the net loss in sales or revenue during the intervention period. Hence, this current study thoroughly extends on the work of [Masena and Shongwe](#page-18-24) [\(2024a\)](#page-18-24) and [Masena and Shongwe](#page-18-25) [\(2024b\)](#page-18-25) by conducting an in-depth intervention analysis by incorporating the pulse function into the fitted SARIMAX models in the intervention period; such an additional analysis assists in quantifying the approximate amount that the economy lost due the intervention period. This is the important component missing in all the publications [\(Makoni and](#page-18-19) [Chikobvu](#page-18-19) [2023a,](#page-18-19) [2023b,](#page-18-20) [2023c;](#page-18-21) [Chipumuro et al.](#page-18-22) [2024;](#page-18-22) [Chikobvu and Makoni](#page-18-23) [2024;](#page-18-23) [Masena](#page-18-24) [and Shongwe](#page-18-24) [2024a,](#page-18-24) [2024b\)](#page-18-25); readers must be made aware of these analyses so policymakers know the approximate amount lost due to an uncontrollable intervention. Then, mitigating strategies can be developed and implemented to lower the negative effects in the future. Furthermore, the intervention analysis uses three approaches to fitting the pulse function to the interrupted series throughout the intervention period for both the wholesale and retail series. Finally, the loss of revenue in both sectors will be quantified using the approach with the best-fitting pulse function.

#### **2. Materials and Methods**

In this study,  $T_k$  represents the intervention period, where  $k = \{0, 1, \ldots, j\}$ .  $T_0$  is the starting point of the intervention and  $T_j$  is the last point in the intervention period.  $Y_t$ represents the response variables: the total monthly (i) wholesale and (ii) retail trade sales.

The step-change variable takes the value of 0 in the pre-intervention period and 1 during the intervention period [\(Cryer and Chan](#page-18-0) [2008\)](#page-18-0). A step function is expressed as follows:

$$
S_t^{T_k} = \left\{ \begin{array}{ll} 0 & \text{if } t < T_k \\ 1 & \text{if } t \geq T_k \end{array} \right\} \tag{1}
$$

The pulse variable takes the value of 1 in the intervention point/period and 0 otherwise [\(Cryer and Chan](#page-18-0) [2008\)](#page-18-0). A pulse function is expressed as follows:

$$
P_t^{(T_k)} = \begin{cases} 0, & \text{if } t \neq T_k \\ 1, & \text{if } t = T_k \end{cases}
$$
 (2)

For any given series, the intervention effect is modelled via the general form of a transfer function as follows [\(Schaffer et al.](#page-19-3) [2021\)](#page-19-3):

$$
Y_t = \mu + \frac{\omega_0 + \omega_1 B + \omega_2 B^2 + \ldots + \omega_h B^h}{1 - \delta_1 B - \delta_2 B^2 - \ldots - \delta_r B^r} X_t + \varepsilon_t
$$
\n(3)

where  $X_t = P_t^{T_k}$  or  $S_t^{T_k}$  (intervention variable), B is the backshift operator  $(B^pY_t = Y_{t-p})$ ,  $\omega_0$ denotes the initial value for the impact of the intervention at  $T_0$ ,  $\delta$  is the decay rate, *h* describes when the effect happens, while *r* represents the decay pattern. When the intervention impact model shows that the intervention had an immediate effect with a gradual decay,  $h = 0$  and  $r = 1$  in Equation (3). However, when the intervention impact model shows that the intervention had a delayed effect with a gradual decay,  $h = 1$  and

 $r = 1$  in (3). Note that  $r = 1$  is a variable used to show that the intervention impact in the series has an exponential decaying pattern or dies out exponentially.

Two parts of the overall model must be obtained to evaluate the impact of the intervention. The first part is the basic model for the pre-intervention series, and the second part is the intervention impact model [\(Bartholomew et al.](#page-18-11) [2023\)](#page-18-11). The evaluation is carried out using the following steps:

- i. Identify  $(T_0)$ , the start of the intervention period;
- ii. Apply the Box–Jenkins methodology to fit an ARIMA model in the pre-intervention period;
- iii. Use the pre-intervention model to forecast values in the intervention period (counterfactual);
- iv. Obtain the differences between actual values in step (iii);
- v. Evaluate step (iv) to determine a model for the intervention effect;
- vi. Use the results from step (v) to select the appropriate intervention variable;
- vii. Use Equation (3) to estimate the intervention effects.

## **3. Results and Discussion**

This section outlines the ARIMA/SARIMA intervention models used to assess and quantify the COVID-19 pandemic effects on the total monthly wholesale and retail trade sales in South Africa. Section [3.1](#page-4-0) summarises the pre-intervention models for the wholesale and retail datasets from the studies by [Masena and Shongwe](#page-18-24) [\(2024a,](#page-18-24) [2024b\)](#page-18-25). Section [3.2](#page-9-0) presents the intervention analysis on the total South African monthly wholesale trade sales from April 2020 to May 2021 and the total South African monthly retail trade sales from April 2020 to October 2020. For both datasets, a pulse function is incorporated into the fitted SARIMA models using three approaches to extend the fitted pre-intervention models. All analyses involving model selection, parameter estimation, and model diagnostics were conducted using the TSA, tseries, forecast and MASS packages in R statistical software version 4.3.2 [\(Cryer and Chan](#page-18-0) [2008;](#page-18-0) [R Core Team](#page-19-7) [2023;](#page-19-7) [Trapletti and Hornik](#page-19-8) [2018;](#page-19-8) [Hyndman](#page-18-26) [and Khandakar](#page-18-26) [2008;](#page-18-26) [Venables and Ripley](#page-19-9) [2002\)](#page-19-9).

## <span id="page-4-0"></span>*3.1. Pre-Intervention Models*

### 3.1.1. Wholesale

The time series plot of the South African Wholesale trade sales from January 2009 until April 2023 is shown in Figure [1.](#page-4-1) *Economies* **2024**, *12*, x FOR PEER REVIEW 6 of 21

<span id="page-4-1"></span>

**Figure 1.** Time series plot of wholesale trade sales. **Figure 1.** Time series plot of wholesale trade sales.

The Box–Cox transformation had a lambda value of  $\lambda = 1.0303 \approx 1$ , which suggested that data transformation was not necessary for the wholesale data. The KPSS test has a highly significant p-value (0.01), which suggests that the series is not trend stationary. Therefore, the first and seasonal differences are necessary to de-trend and capture the seasonality in the series. The KPSS unit root test of stationarity was conducted, and its *p*-value  $\approx 0.1$ ; this means that it is not statistically significant at a 5% significance level. Therefore, the first and seasonally differenced wholesale series in Figure [2](#page-5-0) is trend stationary.

<span id="page-5-0"></span>

Plot of  $\Delta\Delta_{12}$  pre-intervention total wholesale

**Figure 2.** First and seasonally differenced wholesale trade sales series. **Figure 2.** First and seasonally differenced wholesale trade sales series.

Masena and Shongwe (2024a) identified the pre-intervention model for SA's total [Masena and Shongwe](#page-18-24) [\(2024a\)](#page-18-24) identified the pre-intervention model for SA's total monthly wholesale trade sales  $(W_t)$  as  $SARIMA(2, 1, 1)(0, 1, 1)_{12}$  with MLE parameter estimates given in Table 1, [an](#page-5-1)d the model is given by:

$$
(1 - \phi_1 B - \phi_2 B^2)(1 - B)(1 - B^{12})W_t = (1 - \theta_1 B)(1 - \Theta_1 B^{12})\varepsilon_t
$$
 (4)

<span id="page-5-1"></span>**Table 1.** SARIMA $(2, 1, 1)(0, 1, 1)_{12}$  model parameter estimates.

All model parameters in Table [1](#page-5-1) are statistically significant at the 5% significance level. The standardised residuals in Figure [3a](#page-6-0) are random with no apparent trend. The ACF plot in Figure [3b](#page-6-0) suggests no autocorrelation on residuals except for 3 slightly significant lags. The pattern of the histogram of the residuals in Figure [3c](#page-6-0) is almost close to that of normal distribution. Shapiro–Wilk and Jarque–Bera normality tests were conducted at a 5% significance level. The highly significant *p*-values from the Shapiro–Wilk (0.01) and Jarque–Bera (4.006  $\times$  10<sup>-10</sup>) tests suggest that the standardised residuals from the fitted SARIMA model are not normally distributed. According to these tests, the assumption of normality is violated.

Portmanteau Ljung–Box and Box–Pierce tests are used to test for serial autocorrelation in the residuals of the chosen  $SARIMA(2, 1, 1)(0, 1, 1)<sub>12</sub>$  model. The *p*-values from the Ljung– Box (0.108) and Box–Pierce (0.149) tests are not statistically significant at a 5% significance level. Therefore, the null hypothesis cannot be rejected. It is concluded that there is no

autocorrelation in the residuals from the fitted SARIMA model (since only a few lags exceed the standard error limits that are blue in Figure 3b). The slightly significant lags in Figure 3b are due to random sampling error.

normal distribution. Shapiro–Wilk and Jarque–Bera normality tests were conducted at a

<span id="page-6-0"></span>

Figure 3. (a) Residual series plot, (b) ACF, and (c) histogram of standardised residuals from the  $SARIMA(2, 1, 1)(0, 1, 1)<sub>12</sub> model.$ 

In further analysis, the fitted  $SARIMA(2, 1, 1)(0, 1, 1)<sub>12</sub>$  model was investigated for outliers in the pre-intervention period using the R forecast package [\(Hyndman and Khan](#page-18-26)[dakar](#page-18-26) 2008). An Innovative Outlier (IO) was detected at *t*<sub>120</sub> corresponding to December 2018. The presence of the IO explains the violation of the normality assumption. However, the histogram in Figure 4c suggests that the residuals from the SARIMA(2, 1, 1)(0, 1, 1)<sub>12</sub> model might be considered almost normally distributed. The *p*-value from the Ljung–Box  $(0.041)$  test is statistically significant at 5% significance level, suggesting autocorrelation in the residuals; this value is close to 0.05, indicating that the Ljung–Box test will have a non-significant *p*-value at 1% significance level. Moreover, the *p*-value from the Box–Pierce test (0.064) is not statistically significant at 5% significance level. Therefore, there is no notable autocorrelation in the residuals from the fitted SARIMA $(2, 1, 1)(0, 1, 1)_1$ <sub>2</sub> model with the IO.

<span id="page-7-0"></span>

Figure 4. (a) Time series plot, (b) ACF and (c) histogram of standardised residuals of the  $SARIMA(2, 1, 1)(0, 1, 1)<sub>12</sub>$  model with the innovative outlier.

# 3.1.2. Retail 3.1.2. Retail

IO.

The time series plot of total monthly retail sales is given in Figur[e 5](#page-7-1). The series in Figur[e 5](#page-7-1) has an upward trend and exhibits a highly seasonal behaviour. Figure 5 has an upward trend and exhibits a highly seasonal behaviour.

<span id="page-7-1"></span>

**Figure 5.** Time series plot of total retail trade sales (௧) from January 2009 to April 2023. **Figure 5.** Time series plot of total retail trade sales (*Rt*) from January 2009 to April 2023.

stationary, with no apparent trend. The *p*-value (0.01) from the Augmented Dickey-Fuller (ADF) test is statistically significant at the 5% significance level. Therefore, the first and seasonally differenced inverse transformed retail series is stationary. The first and seasonally differenced inverse transformed retail series in Figure [6](#page-8-0) is

<span id="page-8-0"></span>

seasonally differenced inverse transformed retail series is stationary.

**Figure 6.** First and seasonally differenced inverse transformed total retail data pre-intervention. **Figure 6.** First and seasonally differenced inverse transformed total retail data pre-intervention.

Masena and Shongwe (2024b) identified the pre-intervention model for SA's total [Masena and Shongwe](#page-18-25) [\(2024b\)](#page-18-25) identified the pre-intervention model for SA's total monthly retail trade sales  $(R_t)$  as SARIMA $(0, 1, 1)(0, 1, 0)_{12}$  with MLE parameter estimates given in Table [2.](#page-8-1) However, the mathematical expression for  $SARIMA(0, 1, 1)(0, 1, 0)_{12}$  in Masena and Shongwe (2024b) is incorrect. The correct mathematical expression of the [Masena and Shongwe](#page-18-25) [\(2024b\)](#page-18-25) is incorrect. The correct mathematical expression of the  $SARIMA(0, 1, 1)(0, 1, 0)<sub>12</sub>$  model is given by:

$$
(1-B)\left(1-B^{12}\right)Y_t = (1-\theta_1B)\varepsilon_t \tag{5}
$$

where  $Y_t = \frac{1}{R_t}$ , since the Box–Cox transformation suggested an inverse transformation to the retail data [Masena and Shongwe](#page-18-25) [\(2024b\)](#page-18-25). The model parameter in Table [2](#page-8-1) is statistically significant at the 5% significance level.

<span id="page-8-1"></span>**Table 2.** SARIMA $(0, 1, 1)(0, 1, 0)$ <sub>12</sub> model parameter estimates.

The time series plot, the ACF and histogram of standardised residuals from the fitted SARIMA $(0, 1, 1)(0, 1, 0)_{12}$  model is provided in Figure [7.](#page-9-1) The standardised residuals in Figure [7a](#page-9-1) are random with no apparent trend. The ACF plot in Figure [7b](#page-9-1) suggests no autocorrelation on residuals except for 1 significant lag. The pattern of the histogram of the residuals in Figure [7c](#page-9-1) almost resembles that of normal distribution.

The Portmanteau Ljung–Box and Box–Pierce tests are used to test for serial autocorrelation in the residuals of the chosen  $SARIMA(0, 1, 1)(0, 1, 0)<sub>12</sub>$  model. The *p*-values from both the Ljung–Box (0.208) and Box–Pierce (0.264) tests are not statistically significant at 5% significance level. Therefore, there is no autocorrelation in the residuals from the fitted SARIMA $(0, 1, 1)(0, 1, 0)_{12}$  model. Therefore, the SARIMA $(0, 1, 1)(0, 1, 0)_{12}$  model may be used to forecast future retail trade sales.

<span id="page-9-1"></span>

residuals in Figure 7c almost resembles that of normal distribution.

Figure 7. (a) Residual series plot, (b) ACF and (c) histogram of standardised residuals from the  $SARIMA(0, 1, 1)(0, 1, 0)<sub>12</sub> model.$ 

#### <span id="page-9-0"></span>The Portmanteau Ljung–Box and Box–Pierce tests are used to test for serial autocor-*3.2. Intervention Analysis: Wholesale and Retail Sales*

Figure 8 presents a broadened view of t[he](#page-10-0) pandemic impact on both the total monthly wholesale and retail trade sales from March 2020. In Figure  $8a,b$  $8a,b$ , forecasts generated using the pre-intervention model are used as the counterfactual series. That is, how the series would have evolved had the COVID-19 pandemic not occurred. Possible impact models of the COVID-19 intervention on wholesale and retail trade sales are illustrated in Figure [9.](#page-10-1) for the wholesale series to recover from the negative impacts of the pandemic. Therefore, it is concluded that the period from April 2020 to May 2021 is the intervention period in the context of the wholesale data. The Stats SA preliminary statistical release on the South African wholesale sector reported that April 2020 had the worst year-to-year (2019 to 2020) percentage change of  $-42.9\%$  [\(Stats SA](#page-19-10) [2024a\)](#page-19-10). The graphical illustration in Figure [8a](#page-10-0) shows that it took 15 months (April 2020–May 2021)

Moreover, there were positive year-to-year comparisons in September 2020 (1.2%) and December 2020 (2.9%). Most of the year-to-year comparisons in 2021 (2020 to 2021) are relatively better than those reported in 2020, with positive percentage changes in May 2021 (10.6%), April 2021 (82%) and May 2021(45.4%). More importantly, these year-to-year comparisons show that the pandemic had an immediate, negative impact on wholesale trade sales, as depicted in Figure [9a](#page-10-1). On the contrary, the retail series took only 8 months to recover from the pandemic effects. Thus, the intervention period for the retail series is March 2020 until October 2020. from March 2020 until October 2020.

From a different perspective, the Stats SA preliminary statistical release on the retail  $\frac{1}{2022}$ sector reported that April 2020 had the worst year-to-year (2019 to 2020) percentage change of −46.1% [\(Stats SA](#page-19-11) [2024b\)](#page-19-11). There were positive year-to-year comparisons in March 2020 (6.4%), highlighting that the retail sales series felt the negative impact of the pandemic from the second month (1-month lag) in the intervention period, as illustrated in Figure [9b](#page-10-1). September 2020 (1.2%) and December 2020 (2.9%) were reported to have shown positive year-to-year (2019 to 2020) percentage changes.

<span id="page-10-0"></span>

Figure 9. Resulting intervention impact models of (a) wholesale and (b) retail trade sales.

# 3.3. Three Approaches to Fitting a Pulse Function: Wholesale and Retail 3.3.1. Trial-and-Error Approach

A pulse function is fitted on the counterfactual series to assess and model the effect of the pandemic on each observation. Figure [10](#page-11-0) presents the results of the trial-and-error approach to fitting the pulse function.

<span id="page-11-0"></span>(a) Quantifying the Impact of COVID-19 on Wholesale Sales in SA

(b) Quantifying the Impact of COVID-19 on Retail Sales in SA

function by trial-and-error approach.

perfect fit to the wholesale series in the intervention period. The fitted values undeniably mimic the pattern of the actual/observed values in the same timeframe. The results are the same for the retail trade sales in Figure 10b. In this approach, the covariate vector of the fitted pulse function was determined through trial-and-error in R statistical software version 4.3.2, using the '*xreg*' parameter in the *arima* function of the forecast package version 4.3.2, using the '*xreg*' parameter in the *arima* function of the forecast package [\(Hyndman and Khandakar](#page-18-26) [2008\)](#page-18-26). Figure 10. Quantifying the COVID-19 impact on (**a**) wholesale and (**b**) retail trade sales using pulse function by trial-and-error approach.<br>The graphical analysis in Figure 10a shows that the fitted pulse function had a c The graphical analysis in Figure [10a](#page-11-0) shows that the fitted pulse function had a close to

#### (Hyndman and Khandakar 2008). 3.3.2. Estimated Values/Actual Values (Quotient Approach)

The second approach includes finding the covariate vector of the pulse function for each month by dividing the estimated or fitted value from the counterfactual series (forecasts) by the corresponding actual/observed value for that month throughout the intervention period. Figure  $11$  presents the results of the fit from this approach. Figure  $11$ a,b

show that fitting a pulse function in the counterfactual series using the quotient approach does not yield a better fit than the results shown in Figure [10](#page-11-0) by the trial-and-error approach for both sectors. Although the series mimics the overall pattern of actual values in the intervention period, it could not capture the significant loss in sales recorded in April 2020 and a few subsequent points in the intervention period on both datasets.

<span id="page-12-0"></span>

#### (a) Quantifying the Impact of COVID-19 on Wholesale Sales in SA

(b) Quantifying the Impact of COVID-19 on Retail Sales in SA

function by fitted values/observed values approach. **Figure 11.** Capturing the COVID-19 impact on (**a**) wholesale and (**b**) retail trade sales using pulse

3.3.3.  $P_t = 1$ , Where  $t = T_k$  or 0 Otherwise

The third and final approach to fitting a pulse function is expressed in Equation (2), where the covariate vector in the pulse function is assigned a constant value of 1 throughout the intervention period and 0 in the pre-intervention period. This is the most common approach in interrupted time series intervention analysis [\(Pridemore et al.](#page-19-4) 2014; Inyang [et al.](#page-18-5) 2023; [Bartholomew et al.](#page-18-11) 2023). The results are shown in Figure 12. Although the fitted/estimated values from this approach managed to detect the negative impact of the pandemic on the actual trade sales, they do not capture its effect accurately. Figure 12a shows that fitting a pulse function using a constant value of 1 in the covariate vector does not provide a good fit to the wholesale series in the intervention period. The results are worse for the retail data shown in Figure [12b](#page-13-0).

<span id="page-13-0"></span>

# (a) Quantifying the Impact of COVID-19 on Wholesale Sales in SA

 $\mathbf{r} = T_0$  or 0 otherwise. **Figure 12.** Capturing the COVID-19 impact on (**a**) wholesale (**b**) trade sales using  $P_t = 1$ , where

#### *3.4. Approach Selection: Wholesale*

Table 3 summarises the results of model selection and adequ[ac](#page-14-0)y metrics from the three approaches used in fitting the pulse function on the interrupted wholesale series in the intervention period. From the results in Table 3, it is evident that Approach 1 is more appropriate in capturing the impact of the COVID-19 intervention on South African wholesale trade sales, as shown by the lowest Akaike's information criterion (AIC), Bayesian information criterion (BIC), root mean squared error (RMSE) and the mean absolute percentage error  $(MAPE)$  values. Therefore, the model with the pulse function fitted by trial and error can be used to quantify the impact of the COVID-19 intervention on the total monthly wholesale  $\frac{1}{2}$  and  $\frac{1}{2}$  intervention of the impact of the impact of the  $\frac{1}{2}$  intervention on the COVID-19 intervention on the COVID-19 intervention on the COVID-19 intervention on the COVID-19 intervention on the COV trade sales.

<span id="page-14-0"></span>**Table 3.** AIC, BIC, RMSE, and MAPE for three approaches to fitting pulse functions to the wholesale series.

## *3.5. Intervention Effects: Wholesale*

Table [4](#page-14-1) summarises the estimated intervention impact of the COVID-19 pandemic throughout the 15 months of the intervention period (highlighting the detrimental effect on wholesale trade sales). The percentage changes in Table [4](#page-14-1) were calculated using Equation (6), expressed as:

% Change = 
$$
\frac{Fitted\ values_{T_k} - Predicted\ values_{T_k}}{Predicted\ values_{T_k}} \times 100
$$
 (6)

<span id="page-14-1"></span>**Table 4.** Summary of COVID-19 estimated effects during 15 months of the intervention.

As shown in Figure [13,](#page-15-0) the hardest hit month was April 2020, with a 43.4% drop or ZAR 91,017 (million) fewer sales than it would have accumulated in the absence of the pandemic. May 2021 had a significantly high percentage change relative to all other months in the intervention period. This shows that not all months were negatively affected.

<span id="page-15-0"></span>

**Figure 13.** Estimated COVID-19 pandemic on the wholesale trade sales from March 2020 to May **Figure 13.** Estimated COVID-19 pandemic on the wholesale trade sales from March 2020 to May 2021.

### *3.6. Approach Selection: Retail*

Table 5 summarises the results of model selection and adequacy metrics from the three approaches used in fitting the pulse function on the perturbed retail series in the intervention period. Similar to the wholesale series, Approach 1 is more appropriate for capturing the impact of the COVID-19 intervention on South African retail trade sales, as shown by the lowest AIC, BIC, RMSE, and MAPE values. Therefore, the model with the pulse function fitted by trial and error can be used to quantify the impact of the COVID-19 intervention on the total monthly retail trade sales.

<span id="page-15-1"></span>19 intervention on the total monthly retail trade sales. **Table 5.** AIC, BIC, RMSE and MAPE for three approaches to fitting a pulse function for the Retail series.

#### $\overline{27}$  Intermetical Effects.  $R_{ab}$ *3.7. Intervention Effects: Retail*

*3.7. Interv[ent](#page-16-0)ion Effects: Retail* Table 6 summarises the estimated intervention impact of the pandemic on the retail mate series and is graphically indicated in Figure 11. The percentige enarges in taste of the retail sector recorded a 48.1% drop or R43,534 (miltrade series and interest in Figure 14. The percentage changes in Table 6 and the percentage changes in Table 6 and Dion) fewer retail sales than would have been accumulated in the absence of the pandemic in April 2020. This clearly indicates that April 2020 was the hardest-hit month in the In 1 per 2020. This clearly marches that 1 per 2020 was the marches in themat in the intervention period. The plot of the estimated COVID-19 pandemic on the retail trade  $d_{\text{e}}$  is the microscopic indicates that April 2020. This contribution is that April 2020 was the hardest-hit months in  $\alpha$  and  $\alpha$  and sales from March 2020 to October 2020, a total of 8 months, with a collective loss of ZAR<br>87.836 million sales from March 2020 to October 2020, a total of 8 months, with a collective loss of ZAR trade series and is graphically illustrated in Figure [14.](#page-16-1) The percentage changes in Table [6](#page-16-0) 87,836 million.

<span id="page-16-0"></span>**Table 6.** Summary of COVID-19 estimated effects during 8 months in the intervention period.

<span id="page-16-1"></span>

**Figure 14.** Estimated COVID-19 pandemic on the retail trade sales from March 2020 to October 2020. **Figure 14.** Estimated COVID-19 pandemic on the retail trade sales from March 2020 to October 2020.

# **4. Conclusions 4. Conclusions**

This study aimed to estimate and quantify the intervention effects of the COVID-19 This study aimed to estimate and quantify the intervention effects of the COVID-19 pandemic on the South African total monthly wholesale and retail sales using the ARIMA pandemic on the South African total monthly wholesale and retail sales using the ARIMA model with three approaches to fitting a pulse function covariate vector by: (i) trial-and-model with three approaches to fitting a pulse function covariate vector by: (i) trial-anderror, (ii) the quotient of fitted values and actual values (Quotient Approach) and (iii) a error, (ii) the quotient of fitted values and actual values (Quotient Approach) and (iii) a constant value of 1 throughout the intervention period. Model selection and adequacy constant value of 1 throughout the intervention period. Model selection and adequacy metrics (AIC, BIC, RMSE, and MAPE) indicated that the trial-and-error method produced metrics (AIC, BIC, RMSE, and MAPE) indicated that the trial-and-error method produced a covariate vector with the best-fitting pulse function in the intervention period for both a covariate vector with the best-fitting pulse function in the intervention period for both datasets. Thus, the pulse function fitting using trial and error provides a new perspective datasets. Thus, the pulse function fitting using trial and error provides a new perspective on the ITS approach to intervention analysis. Interestingly, this approach has not been used in any studies or literature we consulted.

In this study, it is shown using the pulse function with the trial-and-error method In this study, it is shown using the pulse function with the trial-and-error method that the pandemic had an immediate, severe negative impact on wholesale trade sales, that the pandemic had an immediate, severe negative impact on wholesale trade sales, lasting for 15 months (from March 2020 to May 2021). The retail sales were also negatively lasting for 15 months (from March 2020 to May 2021). The retail sales were also negatively affected, but for 8 months only (March 2020 to October 2020), with a 1-month lag or delay, affected, but for 8 months only (March 2020 to October 2020), with a 1-month lag or delay, suggesting that the series felt the negative effects of the pandemic one month into the suggesting that the series felt the negative effects of the pandemic one month into the intervention period. The 8-month recovery period of the South African retail sector shows intervention period. The 8-month recovery period of the South African retail sector shows it is more resilient than the wholesale sector. In the analysis, it was shown that sales in both sectors were hardest hit in April 2020, with an estimated loss of ZAR 91,017 million and

ZAR 43,534 million for the wholesale and retail trade sales, respectively. This is attributed to the implementation of the strict national lockdown, which came into effect on 27 March 2020 in South Africa. Furthermore, this is reflected by the extremely low year-to-year (2019–2020) comparisons and percentage changes between the counterfactual forecasts and the actual/observed values. In the intervention period, the total estimated losses in sales for the wholesale and retail sectors were ZAR 302,339 and ZAR 87,836 million, respectively, indicating that the wholesale industry had the worst losses.

The results of this study will strengthen the goal/objective to provide accurate and reliable forecasting techniques and approaches to quantifying the net effect of large-scale interventions on the two South African sectors. Given the importance of the wholesale and retail trade sectors in the South African economy (which accounts for a significant portion of the GDP and workforce), these intervention quantification efforts will aid businesses and policymakers in assessing the effectiveness of their countermeasures and allow them sufficient time to improve and allocate their resources efficiently to prepare for future shocks or interruptions. Using a time-series approach, one can analyse the trend of wholesale and retail trade sales before, during, and after the COVID-19 pandemic to identify the extent of the shock and forecast the industry's future sales trajectory.

As part of future work, other researchers can reevaluate the work discussed in [Makoni](#page-18-19) [and Chikobvu](#page-18-19) [\(2023a,](#page-18-19) [2023b,](#page-18-20) [2023c\)](#page-18-21), [Chipumuro et al.](#page-18-22) [\(2024\)](#page-18-22), and [Chikobvu and Makoni](#page-18-23) [\(2024\)](#page-18-23) to fit the pulse function model discussed here to conduct a proper quantification analysis of the intervention effect by estimating the actual loss in sales or revenue during the intervention (i.e., GFC or COVID-19) period in the South African economy. In addition, other alternative models may be more appropriate in the model selection process; some of these include hybrid models and machine learning methods. These can be pursued as future research and compared with the fitted model here.

#### **5. Study Limitations**

This study did not provide wholesale and retail trade sales forecasts in the postintervention period using the selected ARIMAX intervention models. Moreover, the retail trade sales appear to have been subjected to a second intervention from June to July 2021; however, this plausible intervention was not investigated because the scope of this research was to assess the initial effect of COVID-19 on the two sectors in South Africa.
