**Abstract:** Heterogeneous phase composite (HPC) flooding technology that is based on branchedpreformed particle gel (B-PPG) is an important technology for enhancing oil recovery in high watercut reservoirs. In this paper, we conducted a series of visualization experiments under the condition of developed high-permeability channels after polymer flooding, with respect to well pattern densification and adjustment, and HPC flooding and its synergistic regulation. The experiments show that for polymer-flooded reservoirs, HPC flooding can significantly reduce the water cut and increase oil recovery, but that the injected HPC system mainly advances along the high-permeability channel with limited sweep expansion. Furthermore, well pattern densification and adjustment can divert the original mainstream direction, which has a positive effect on HPC flooding, and can effectively expand the sweeping range under the synergistic effect of residual polymers. Due to the synergistic effect of multiple chemical agents in the HPC system, after well pattern densification and adjustment, the production time for HPC flooding with the water cut lower than 95% was significantly prolonged. In addition, conversion schemes, in which the original production well is converted into the injection well, are better than non-conversion schemes in terms of expanding sweep efficiency and enhancing oil recovery. Therefore, for well groups with obvious high-water-consuming channels after polymer flooding, the implementation of HPC flooding can be combined with well pattern conversion and intensification in order to further improve oil displacement.

**Keywords:** polymer flooding; heterogeneous phase composite system; branched-preformed particle gel; image processing; sweep efficiency

### **1. Introduction**

The mature waterflooding oilfields in eastern China are mainly terrestrial sedimentary sandstone reservoirs with complex structures and serious heterogeneity [\[1](#page-21-0)[,2\]](#page-21-1). After decades of waterflooding development, the water injectivity of each layer varies greatly, resulting in small swept volumes, and the injected water often advances along the high-permeability layers with a high degree of water flooding and low movable oil saturation. The remaining oil distribution is highly dispersed and locally concentrated [\[3,](#page-21-2)[4\]](#page-21-3).

Polymer flooding technology has become an important means of enhancing oil recovery in China's high water-cut oilfields and has been applied in large-scale industrial applications in the Shengli and Daqing oilfields [\[5,](#page-21-4)[6\]](#page-21-5). Studies have shown that polymer flooding can effectively expand the swept volume and improve displacement efficiency. After polymer flooding, the final oil recovery can generally reach 40–50%, an increase of 7–15% compared with water flooding [\[7\]](#page-21-6). However, approximately 50% of the crude oil still remains underground, representing a significant opportunity to further improve oil

recovery [\[8–](#page-21-7)[10\]](#page-21-8). After polymer flooding, the reservoir heterogeneity is generally further intensified, and the distribution of the remaining oil is more scattered. Subsequently, injected fluids easily form ineffective channeling along dominant zones, which seriously affects the expansion of the swept volume. In addition, the residual polymer can become stuck in the low-permeability zone, which hinders contact between the subsequent oil displacement agents and the crude oil surface, leading to the "secondary sweep problem" [\[11,](#page-21-9)[12\]](#page-21-10). This poses a great challenge to the deep development of reservoirs after polymer flooding.

Many scholars have investigated methods for further improving oil recovery after polymer flooding, including through foam flooding [\[13](#page-21-11)[,14\]](#page-21-12), alkali–surfactant–polymer (ASP) flooding [\[15\]](#page-21-13), gel treatment [\[16\]](#page-21-14), nanoparticle treatment [\[17\]](#page-21-15), etc.; nevertheless, these technologies present defects, such as being easily flushed by injected water, and poor stability. Heterogeneous phase composite (HPC) flooding technology that is based on branched-preformed particle gel (B-PPG) is an important technology for enhancing oil recovery in ultra-high water-cut reservoirs, and has been shown to effectively increase oil recovery and prolong production time [\[18–](#page-21-16)[20\]](#page-21-17). B-PPG is obtained by the cross-linking reaction of the main chemical agent, which cross-links the agent and initiator under certain conditions, followed by processing after drying, crushing and sieving. The particles have strong viscoelasticity, good suspension and deformability, and can maintain stability in most reservoirs and various water formations. [\[21,](#page-21-18)[22\]](#page-21-19). Research has shown that the main mechanism of B-PPG is to block cracks, leading to water diversion [\[23,](#page-21-20)[24\]](#page-21-21). When injected into the formation, the water-swelling particles can pass through pore throats of a smaller diameter than themselves, and block high-permeability channels, thereby expanding the subsequent water-sweeping area [\[25–](#page-22-0)[27\]](#page-22-1). In order to better employ the plugging effect of B-PPG, Cui [\[28\]](#page-22-2) designed a heterogeneous phase composite flooding (HPCF) system that was composed of a polymer, surfactant and B-PPG. Experiments have shown that compared with polymer flooding, HPFC can further expand the swept range and improve oil recovery.

Well pattern adjustment is another conventional method of oil production in unswept areas [\[29](#page-22-3)[–32\]](#page-22-4). This method can effectively improve flow field distribution by infilling and transferring wells, that is, to adjust the original injection–production well pattern by infilling injection–production wells locally or by transferring production wells into injection in areas with an imperfect injection–production relationship, thereby producing more remaining oil in areas that are not easily swept by the HPCF system; this significantly reduces the underground oil saturation of reservoirs [\[33\]](#page-22-5).

Since the distribution of the remaining oil changes greatly after polymer flooding and the pore structure is more complex [\[34\]](#page-22-6), it is difficult to meet the demand for further the significant enhancement of oil recovery. In recent years, many scholars have studied technologies to further enhance oil recovery after polymer flooding. Gao et al. evaluated the synergistic effect of PPG and ASP after polymer flooding using micro-displacement experiments [\[35\]](#page-22-7); they concluded that the synergy of PPG and ASP can not only further improve oil recovery, but also reduce polymer consumption and improve economic benefits. Gong et al. investigated a combined B-PPG and hydrolyzed polyacrylamide (HPAM) system; they found that the synergistic displacement effect was better than that of any single agent and further enhanced oil recovery after polymer flooding [\[36\]](#page-22-8). Li et al. performed core displacement experiments on an enhanced foam flooding system that was composed of a polymer, foam agent and nitrogen after polymer flooding [\[37,](#page-22-9)[38\]](#page-22-10); they confirmed that the system could effectively improve reservoir stability, and that the improvement in the injection profiles could significantly enhance oil recovery. Although these methods significantly improved the oil displacement efficiency, they are still very limited in producing remaining oil in unswept areas. Therefore, research on a combination of the HPC system and a well pattern adjustment (WA) has attracted extensive attention. Sun et al. studied the synergistic effect of streamline adjustment and HPC flooding after polymer flooding [\[39](#page-22-11)[,40\]](#page-22-12). This method adjusts the well pattern after polymer flooding to produce crude oil in the unswept areas and increase the action range of the HPC system, thereby significantly

expanding the swept area and enhancing oil recovery. After synergistic application, the mainstream direction changes and the injection pressure also increases, which leads to an election as during after polymer flooding, and further study the effective study the effective study the effective study the effecti obvious reduction in the water cut and enhancement in the oil recovery. However, the existing HPC systems are rarely applied in the field, and their displaceexpanding the swept area and emiliancing on recovery. After synergistic application, the

However, the existing HPC systems are rarely applied in the field, and their displacement evaluation is limited. It is, therefore, necessary to focus on the characteristics of highly developed dominant channels after polymer flooding, and further study the effect of well pattern adjustment and HPC flooding on the dynamic sweep regulation, as well as the synergistic mechanism that is involved in expanding the sweep with the residual polymer.

In this paper, we report on an HPC flooding pilot test block after polymer flooding and well pattern adjustment, performed based on the characteristics of the Shengli Oilfield in China. We conduct a series of visualization experiments after polymer flooding using a two-dimensional sand pack visual displacement device. We investigate the dynamic sweep characteristics of well pattern densification and adjustment, HPC flooding and their synergistic regulation under the condition of developed high-permeability channels. In addition, we explain the influence of dominant high-permeability channels, residual lines of the large-scale and beneficial development of the large-scale and beneficial development of the large-scale and beneficial dev polymers and well pattern adjustment after polymer flooding on the dynamic sweep of HPC polymers and wen pattern adjustment after polymer hooding on the dynamic sweep of FITC flooding, and provide theoretical guidance for the large-scale and beneficial development of similar reservoirs after polymer flooding.

### 2. Results and Discussion

## 2.1. Dynamic Sweep Evaluation in HPCF Experiments

In our experiments, we designed a five-point well pattern unit, consisting of one injection well and one production well; this was based on the actual well pattern characteristics of polymer flooding in the Shengli Oilfield [\[18\]](#page-21-16). The five-point well pattern unit was then used to design strongly heterogeneous and weakly heterogeneous models (Figure [1\)](#page-2-0). In this figure, the green circle represents the injection well, and the red circle represents the production well. The weakly heterogeneous model was filled with glass microspheres of<br>of an average size of 60 mesh, while the strongly heterogeneous model was filled with glass an average size of 60 mesh, while the strongly heterogeneous model was filled with glass microspheres of an average size of 40 mesh in the high-permeability zone and 80 mesh in the high-permeability zone and 80 mesh in the low-permeability zone. The average porosities of these two models were 33.5% and 34.8%, respectively.

<span id="page-2-0"></span>

#### 2.1.1. Visual Experimental Results

From the displacement processes in Figure [2,](#page-3-0) it can be seen that in the weakly heterogeneous model, the injected water displacement was relatively balanced in the water flooding stage, and there were some unswept areas at the edge of the model. In the polymer flooding stage, after the injection of the polymer solution, the viscosity of the injected water

<span id="page-3-0"></span>increased and the water-oil mobility ratio improved. Coupled with its viscoelastic effect, this dragged the blind terminal and droplet residual oil at the edge of the pores along, thereby forming a stable oil channel. In the area swept by the polymer front, the displaced residual oil was enriched with time. The advance of the polymer front was relatively balanced, and there were few unswept areas between the injection and production wells.

(**c**) Initial stage of polymer flooding. (**d**) stage of water flooding. (b) End stage of water flooding. (c) Initial stage of polymer flooding. (d) End stage of polymer flooding.

<span id="page-3-1"></span>However, for the strongly heterogeneous model, it can be seen from Figure [3 t](#page-3-1)hat in the water flooding stage, the injected water was mainly displaced along the high-permeability channel and had a very limited dynamic sweeping area. In the polymer flooding stage, the massive polymer aggregation increased the seepage resistance of the high-permeability channel, which expanded the sweeping range of the subsequent injected water and achieved balanced water flooding; however, there was still a large amount of oil remaining in the marginal area. The sweep expansion effect of the strongly heterogeneous model was worse than that of the weakly heterogeneous model.

Figure 3. Water flooding and polymer flooding processes in strongly heterogeneous model. (a) Initial stage of water flooding. (b) End stage of water flooding. (c) Initial stage of polymer flooding. (d) End stage of water hooding.

As shown in Figure [4,](#page-4-0) in the weakly heterogeneous model, after polymer flooding, the injected HPC system blocked the pore throats, and changed the direction of the subsequently injected water, thus expanding the sweep efficiency and effectively utilizing the residual oil in the unswept area. In contrast, in the strongly heterogeneous model, it can be seen from Figure [5](#page-4-1) that the HPC system established a good frictional resistance along the high-permeability channel, which forced more injected water to divert and to spread into the marginal low-permeability zone.

## 2.1.2. Evaluation of Sweep Efficiency 2.1.2. Evaluation of Sweep Efficiency 2.1.2. Evaluation of Sweep Efficiency

The sweep efficiency is a very important factor affecting reservoir recovery [\[41\]](#page-22-13) and can intuitively reflect the sweep degree of the displacement phase. At present, the determination methods for sweep efficiency include the core test method and the numerical simulation method. Of these, the core test method cannot intuitively display the swept position of the displacement phase, while the numerical simulation method cannot accurately describe the swept range for the actual model. In addition to these two methods, image processing technology for a visual model has also been applied for the determination of sweep efficien[cy](#page-22-14) [42]. Compared with traditional methods, the image processing method can divide the swept areas conveniently and intuitively. A flowchart showing the image processing technology is provided in Figur[e 6](#page-4-2). By graying the obtained images [43-[45\]](#page-22-16) and then thresholding the images according to the two-dimensional Otsu image threshold segmentation algorith[m \[4](#page-22-17)6], an appropriate grayscale image threshold was selected; then, the target and background were segmented via the grayscale threshold (Figure [7\)](#page-5-0) so as to convert the grayscale image into a binary image that could reflect its local and overall characteristics.

Figure [8 s](#page-5-1)hows the stacked diagrams of the sweep efficiency that were obtained by processing the images and then using MATLAB to determine the effective sweep range of the model. It can be seen that the HPC system can effectively improve sweep efficiency. Due to the good viscoelasticity and plugging properties of the HPC system, the subsequent injected water diverted more to both sides of the mainstream area, thereby completely sweeping the weakly heterogeneous model, and significantly improving the swept range of the strongly heterogeneous model. The sweep efficiencies of the weakly and strongly heterogeneous models after HPC flooding were 98.45% and 79.87%, respectively, and compared with those after polymer flooding, increased by 5.93% and 8.99%, respectively.  $\mathbf{t}$ processions are station ungrants of the sweep effective that were obtain

## 2.1.3. Water Cut and Recovery 2.1.3. Water Cut and Recovery 2.1.3. Water Cut and Recovery

Via an analysis of the water cut and the recovery factor of the different heterogeneous models (Figure [9 a](#page-6-0)nd Table 1[\), it](#page-6-1) can be seen that the water cut decreased significantly in the polymer flooding stage, and the recovery factor increased significantly. In the strongly heterogeneous model, the high-permeability channel produced less excess oil in each displacement stage, which limited the enhancement of the recovery factor and the extension of the recovery time. The recovery factors for the weakly and strongly heterogeneous models after polymer flooding were 60.13% and 42.02%, respectively. The HPC system significantly reduced the water cut and enhanced the oil recovery. The water cut for the two models dropped to 63.64% and 60.87%, respectively, and compared with those after polymer flooding, their recovery factors after HPC flooding increased by 13.97% and 11.43%, respectively. However, the increase in the sweep efficiency was limited, ranging from 5.93% to 8.99%. Especially for the strongly heterogeneous model, the sweep efficiency was only 79.87% after HPC flooding, meaning that there is still huge potential to further improve the oil recovery.

<span id="page-6-0"></span>

<span id="page-6-1"></span>

#### *2.2. Dynamic Sweep Evaluation in WAF Experiments*

The efficient development of unswept remaining oil is the key to improving oil recovery [\[39\]](#page-22-11). After HPC flooding, due to the high-permeability channel between the injection and production wells, there was still a large amount of oil remaining in the non-mainstream areas, with a limited increase in the sweep efficiency, especially for the strongly heterogeneous model. Well pattern densification and adjustment (WA) is an effective measure by which to change the flow field direction, forcibly utilize the remaining oil and expand

<span id="page-7-0"></span>the sweep efficiency. In order to study the influence of different WA schemes on the oil displacement effect after polymer flooding, five post-polymer flooding schemes were de-signed for the strongly heterogeneous model (Figure [10\)](#page-7-0). The five schemes were divided into non-conversion schemes, Schemes 1, 2 and 3, and conversion schemes, Schemes 4 and 5, with the original production wells, W1 in Schemes 4 and 5, being converted into injection wells.

heterogeneous model. Well pattern densification and adjustment (WA) is an effective

Figure 10. Well pattern densification adjustment schemes. (a) Original well location. (b) Scheme 1. (c) Scheme 2. (d) Scheme 3. (e) Scheme 4. (f) Scheme 5. Arrow represents flooding direction.

## 2.2.1. Visual Experimental Results 2.2.1. Visual Experimental Results

For the non-conversion schemes, as shown in Figures [11](#page-8-0)[–13,](#page-8-1) after the well pattern adjustment, most of the injected water from the original injection well still flushed along adjustment, most of the injected water from the original injection well still flushed along the high-permeability channel, and under the action of the residual polymer, the water the high-permeability channel, and under the action of the residual polymer, the water injected from the new well effectively expanded the sweep efficiency. However, after the injected from the new well effectively expanded the sweep efficiency. However, after the injected water from the new injection well pushed the residual polymer into the high-injected water from the new injection well pushed the residual polymer into the highpermeability channel, its seepage resistance increased, and due to the diversion effect between the injection wells, more injected water was diverted in the direction of the new production wells. Under the synergistic effect of the residual polymer, the sweeping range effectively expanded and the balanced displacement of the remaining oil was realized.

Figures [14](#page-9-0) and [15](#page-9-1) show the experimental results of the two conversion schemes (Schemes 4 and 5). After infilling two production wells, the direction of the original mainstream was disrupted, and the original non-mainstream area became the mainstream area. Injected water preferentially displaced through the high-permeability channel and then diverted due to the diversion effect between the injection wells. Since a large amount

of polymer remained near the high-permeability zone after polymer flooding, the diversion of the injected water to the oil well expanded the action range of the residual polymer, resulting in a more balanced displacement effect. After the injected water broke through, the formation of the mainstream displacement path effectively expanded the swept range of water flooding, and the remaining oil in the unswept areas was effectively produced. These five WAF schemes could effectively utilize the remaining oil in the unswept areas, and the conversion of the production well could change the original mainstream direction. production we were senergied to the synergial polymer the synergies range  $\frac{1}{2}$  range range. effective conversion of the production wen could enarge the original manipulatin directive

The changes in the sweep efficiency at different flooding stages are shown in Figure 16a. After polymer flooding, the well pattern adjustment could effectively utilize the remaining<br> oil in the unswept areas. For the non-conversion schemes, since the original injection and  $\overline{\phantom{a}}$  $\overline{m}$ , and  $\overline{m}$ ,  $\overline{m}$ , the direction wells, the original main-direction of the original main-direction of the original mainstructually and the original non-mainstream area became the main stream and main area became the mainstream are The changes in the sweep efficiency at different flooding stages are shown in Figure 16a. After polymer flooding, the well pattern adjustment could effectively utilize the remaining oil in the unswept areas. For the non-conversion schemes, since the original injection and

production wells had not changed, the injected water from the original or new injection well preferentially flushed along or toward the high-permeability channel, and under the effect of the residual polymer and diversion line, the swept area of injected water further expanded. The larger the flow field transition angle after well pattern adjustment, the higher the sweep efficiency. After the well pattern adjustment, the flow field transition angle in Scheme 2 was obviously the smallest, as the sweep efficiency was 97.82%. For the conversion schemes, after converting the original production well to the injection well and infilling another two new production wells, the mainstream direction of the original flow field was broken, and the original non-mainstream area became the mainstream area, which effectively expanded the sweeping range of the injected water. The larger the flow field transition angle after the well pattern adjustment was, the better the expanded sweep of water flooding was. The conversion of the production well could change the original mainstream original mainstream original mainstream or  $\alpha$  $\alpha$  were not the production  $\alpha$

As shown in Figures [16b](#page-10-0) and [17,](#page-12-0) after well pattern adjustment, the recovery factor for each scheme improved to a certain extent. In the non-conversion schemes, due to the ineffective water displacement along the high-permeability channel, although the water cut decreased after the well pattern adjustment, the decrease was so limited as to result in a small increase in the recovery, as shown in Figure  $17a-c$ . Among the nonconversion schemes, Scheme 3 had the highest enhanced oil recovery (EOR) value at 15.87%, followed by Scheme 2 with an EOR value of 13.84%, and Scheme 1 with the lowest EOR value at 10.83%. However, for the conversion schemes, the mainstream area significantly increased after the transfer injection, and under the synergistic effect of residual polymers, the water cut decreased significantly compared with those non-conversion schemes, as shown in Figure [17d](#page-12-0), e. There was a certain period of anhydrous or extremely low water cut production in both schemes, and their recoveries significantly improved. As new seepage channels were formed after the injected water broke through, the water

mainstream area, which effectively expanded the sweeping range of the injected water.

cut increased rapidly, and the development characteristics of the high-water-consumption **88.64** 60 zones became obvious. After well pattern adjustment, the conversion schemes improved **97.82 52.69** 40 the oil recovery significantly better than the non-conversion schemes. The recovery factors of the two conversion schemes after polymer flooding increased by 22.3% and 17.71%, respectively. Furthermore, after polymer flooding, the effective production time in all five WAF experiments was shorter than that in the HPCF experiment (960 s, as shown in **28.37 21.02 15.87 22.3** Figure [9b](#page-6-0)), ranging from 420 s to 720 s.

## 2.3. Dynamic Sweep Evaluation in WAHPCF Experiments

Although the sweep efficiency increased after well pattern densification and adjustment, after the injected water broke through, the water cut rose rapidly, seriously affecting the effective production time. After water flooding, the oil saturation in the original unswept area was still high, and the displacement efficiency was low [36]. According to previous experiments [39], [the](#page-22-11) HPC system effectively blocked the dominant channels, expanding the water flooding range, and the well pattern densification and adjustment expanded the scope of the HPC system, which played a guiding role in the HPC system. In order to study the influence of the HPC system under different well patterns, five WAHPCF schemes were designed on the basis of well pattern densification and adjustment.

### *2.3. Dynamic Sweep Evaluation in WAHPCF Experiments* 2.3.1. Visual Experimental Results

For the non-conversion schemes (Schemes 1, 2 and 3), the injected HPC system from the injection well mainly plugged along the high-permeability channel, while the equilibrium displacement of the remaining oil occurred in the unswept areas, driving the remaining oil towards the high-permeability channel and production wells. In the subsequent water flooding stage, under the synergistic effect of the residual polymers and the injected HPC system, the flushing of injected water along the high-permeability channel was prevented; in addition, the flow resistance of the injected water from the new wells was increased, making it difficult to break through into the high-permeability channel. More subsequently injected water flowed to the new production wells and displaced the remaining oil in the original unswept areas, further expanding the sweeping range of the water flooding. It (Figure [19\)](#page-13-1) was closer to the high-permeability channel, and the injected water was more likely to break through the HPC system and enter the high-permeability channel, forming<br> the internal main displacement plut, that is, more injectively water from the help injection while entered the high permeability channel and flowed to the original production well. A large incident of the HI e system highered from the new highered wen remained at the edge of the model. Although the model was completely swept, its oil displacement efficiency was die meden Thinough the meder was completely swept, his on displacement emerging was obviously low. In addition, the new production well was closer to the high-permeability  $\theta$  system, the flux discussed water along the flux discussed water along the high-permeability channel was pre-flux discussed w channel, with a smaller displacement pressure difference and a displacement effect that<br>was less halanced than that in Schame 1 can be seen that, compared with Scheme 1 (Figure [18\)](#page-13-0), the new injection well in Scheme 2 a new main displacement path; that is, more injected water from the new injection well amount of the HPC system injected from the new injection well remained at the edge of was less balanced than that in Scheme 1.

In Scheme 3 (Figure [20\)](#page-13-2), after infilling two wells based on Scheme 1, the mainstream direction of the original flow field changed and expanded the action range of the HPC flooding. For the conversion schemes (Schemes 4 and 5), after converting the original production well and infilling two production wells, the mainstream direction of the flow field changed, and the injected HPC system formed an effective plug from both ends of the high-permeability channel, as shown in Figures [21](#page-14-0) and [22.](#page-14-1) Under the synergistic effect of the residual polymer and diversion lines, the subsequently injected water displaced the remaining oil to the production wells in a relatively balanced manner, enlarging the swept area to the entire range of the model. Compared with Scheme 5, a large amount of the HPC system remained near the high-permeability channel, and its plugging effect was not effectively exerted, resulting in unbalanced water flooding. Furthermore, it can be clearly seen that the displacement path of the subsequent water flooding first runs

<span id="page-13-0"></span>

along the high-permeability channel and is then diverted to the production wells at the diversion line. (**c**) Initial stage of water in  $\mathbf{c}$  water in  $\mathbf{c}$  arrows represent in  $\mathbf{c}$  arrows represent in  $\mathbf{c}$  and 95%. <span id="page-13-2"></span>

## 2.3.2. Quantitative Results Analysis

From the sweep efficiency changes at different flooding stages for the five schemes shown in Figure [23a](#page-14-2), it can be seen that after polymer flooding, the well adjustment combined with HPC flooding not only significantly utilized the oil in the unswept areas, but also deeply excavated the remaining oil. Compared with the WAF experiments, under the same well pattern adjustment conditions, the sweep efficiencies of the five schemes

<span id="page-14-0"></span>achieved 100% after HPC flooding, which indicates that the well pattern adjustment had a positive effect on the HPC flooding. achieved 100% after HPC flooding, which indicates that the well pattern adjustment had a HPC injection. Figure 23. Sweep efficiency and recovery in WAHPCF experiments. (a) Sweep efficiency. (b) Recovery.

The water cut and recovery changes for HPC flooding after different well pattern adjustment schemes are given in Figures [23b](#page-14-2) and [24.](#page-16-0) After polymer flooding, the model recovery for each scheme was between 45.82% and 52.64%, and after HPC flooding, it was above 72.67%, with a maximum of 80.97%. Due to the positive effect on HPC flooding following the well pattern adjustments, the water cut reduction in each WAHPCF scheme increased significantly after polymer flooding; the recovery factor also improved greatly, with an increase of more than 23.8 percentage points. Compared with the WAF scheme under the same densification and adjustment conditions, recovery significantly improved. In addition, due to the synergistic effect of multiple chemical agents in the HPC system, the production time for HPC flooding with a water cut lower than 95% was significantly prolonged after well pattern densification and adjustment, as shown in Figure [24](#page-16-0) Comparisons between the conversion scheme and the non-conversion scheme show that after well pattern densification and adjustment, the conversion scheme was better than the non-conversion scheme in enhancing oil recovery. Among the schemes, Scheme 5 had the highest EOR value at 28.33%; this was followed by Scheme 3 with an EOR value of 26.92%, and Scheme 2 with the lowest EOR value at 23.8%.

## **3. Conclusions**

According to the characteristics of the HPC flooding pilot test block in the Shengli Oilfield, we focused on the characteristics of highly developed dominant channels after polymer flooding, and conducted a series of visualization experiments of well pattern densification and adjustment, HPC flooding and their synergistic regulation, using a twodimensional sand pack visual displacement device. The main conclusions are as follows:

- 1. For the reservoirs after polymer flooding, HPC flooding can block the mainstream channel, and significantly increase oil production; however, the injected HPC system mainly advanced along the high-permeability channel between the injection and production wells, and there was still a large area of unswept remaining oil at the edge of the model, with a limited sweep expansion;
- 2. Well pattern densification and adjustment have a positive effect on HPC flooding, which can divert the original mainstream direction after polymer flooding, and effectively expand the sweeping range. After well pattern densification and adjustment, under the synergetic effect of residual polymers and multiple chemical agents in the HPC system, the water cut reduction significantly increased after polymer flooding;
- 3. Conversion schemes were better than non-conversion schemes in terms of expanding the sweep efficiency and enhancing oil recovery. After converting the original production well to an injection well and infilling new production wells, the mainstream direction of the original flow field was broken. The injected water was displaced along the high-permeability channel and diverted to the unswept area, effectively expanding the sweeping range of injected water.

## **4. Materials and Methods**

#### <span id="page-17-0"></span>*4.1. Experimental Apparatus*

The two-dimensional sand pack visual displacement device that was used is shown in Figure [25.](#page-17-0) The device comprises a positive displacement pump that can maintain a constant flow and speed, an experimental console, a syringe, an LED light, a high-resolution camera, a measuring cylinder, a computer acquisition and processing system, and a plane sand pack model.

**Figure 25.** Equipment for visual displacement. **Figure 25.** Equipment for visual displacement.

Figur[e 26](#page-18-0) shows the plane sand pack model, which is composed of two glass plates, Figure 26 shows the plane sand pack model, which is composed of two glass plates, one upper and one lower, that are 2 cm thick each. There is a groove in the lower plate where the epoxy resin rubber ring is placed. The overall size of the model is 35 cm  $\times$  35 cm, wherein the sand pack area is 28 cm  $\times$  28 cm, and 3 mm thick. In addition, the model

## *4.2. Experimental Materials 4.2. Experimental Materials*

Polymer: In this study, the polymer provided by the Shengli Oilfield was partially  $\frac{1}{2}$ hydrolyzed polyacrylamide (HPAM) with a molecular weight of  $2.0 \times 10^7$  and with a relative molecular weight of 20  $55\%$ , solid centent. The concentration of the nolumer solution prepared with ultrapure water was 1000 mg/L, and an automated high-pressure and high-temperature viscometer (AMETEK Chandler Engineering, model 5550) was used to test the rheology of the polymer solution at room temperature. As shown in Figure [27,](#page-18-1) the polymer solution had good rheology at room temperature, and its apparent viscosity decreases with the increase in the shear rate. relative molecular weight of 89.55% solid content. The concentration of the polymer

<span id="page-18-1"></span>

**Figure 27.** Relationship between apparent viscosity and shear rate of the polymer solution. **Figure 27.** Relationship between apparent viscosity and shear rate of the polymer solution.

B-PPG: The experimental B-PPG was used in the north area of the Shengli Oilfield; it had an elastic modulus of 10.3 Pa and a particle size of 100–150 mesh. The dry powder B-PPG is shown in Figure [28.](#page-19-0)

<span id="page-19-0"></span>

**Figure 28.** Dry powder B-PPG. **Figure 28.** Dry powder B-PPG.

Surfactant: The experimental surfactant provided by the Shengli Oilfield was petroleum sulfonate (molecular formula:  $\rm{C_{23}H_{38}SO_{3}M}$ ).

Displacement water: The experimental displacement water was ultrapure water. Displacement water: The experimental displacement water was ultrapure water.

Oil: The experiments used a simulated oil configured with industrial lubricating oil Oil: The experiments used a simulated oil configured with industrial lubricating oil and kerosene, with a viscosity of 50 mPa·s and a density of 0.83  $\rm g/cm^3$ .

Dyeing agents: Two dyeing agents, namely methyl orange (molecular formula: Dyeing agents: Two dyeing agents, namely methyl orange (molecular formula:  $\rm C_{14}H_{14}N_3NaO_3S$ ) and methyl blue (molecular formula:  $\rm C_{37}H_{27}N_3Na_2O_9S_3$ ), were used in the experiment to dye the experimental displacement water and HPCF system, as shown Figure 29. in Figure [29.](#page-19-1)
