**Abstract:** Corridors play an important role in the mechanized production of fruits and vegetables in solar greenhouse clusters. A corridor structure that is suitable for the automated production of solar greenhouse clusters is designed in this paper. To increase the corridor's ventilation efficiency and enhance the temperature environment, the computational fluid dynamics method is applied to analyze the effects of corridor structure, ventilation mode, wind speed, and direction on internal temperature and humidity. Studies have indicated that an erroneous layout of the corridor structure may result in the formation of accumulated temperature and heat concentration inside, and ventilation within the corridor is essential. The corridor's ideal dimensions are 3.2 m high by 5 m wide, and it has an internal wind speed and cooling rate that are superior to other structural factors. The ventilation method adopts a combination of top and bottom ventilation, and when the bottom window opening is 70%, there is a good ventilation effect inside the corridor. The corridor has an excellent ventilation effect when the wind speed is  $2 \text{ m/s}$  and the wind direction is east or west. This study supports the intensive and sustainable growth of greenhouse vegetable production by providing guidance for the planning and corridor design of solar greenhouse clusters.

**Keywords:** solar greenhouse cluster; mechanized corridor; combined ventilation; accumulated temperature; flow field

### **1. Introduction**

In modern architecture, a corridor is an overhead connection that meets both functional and aesthetic requirements for two or more high-rise buildings. Corridors are also used in agricultural production. Crops cannot be grown in open fields in northern China due to the harsh winters. In these areas, annual fruit and vegetable production is possible thanks to solar greenhouses [\[1\]](#page-10-0). Chinese solar greenhouses typically include a transparent front roof, a back roof, a back wall, and two side walls. The transparent front roof can generate the greenhouse effect, while the back wall can store excess energy during the day and release it at night. Through these principles, Chinese solar greenhouses greatly reduce energy input. However, the cold weather greatly reduces the connectivity of greenhouses. The issue of poor greenhouse connectivity can be effectively resolved and the integration of production, transportation, and management of solar greenhouse clusters can be facilitated using corridors to connect multiple solar greenhouses in series [\[2\]](#page-10-1). Typically, corridors use transparent glass or plastic film as the covering material, which results in concentrated and uneven temperature under sunlight [\[3\]](#page-10-2), which is not conducive to the work of production

This article is an open access article distributed under the terms and conditions of the Creative Commons Attribution (CC BY) license [\(https://](https://creativecommons.org/licenses/by/4.0/) [creativecommons.org/licenses/by/](https://creativecommons.org/licenses/by/4.0/)  $4.0/$ ).

personnel. Therefore, it is essential to appropriately plan the corridor's structure and enhance its ventilation capabilities for the intended use [\[4–](#page-10-3)[6\]](#page-10-4).

Since most existing solar greenhouses are standalone structures, it is impossible to load or unload fruits or seedlings when it is raining or snowing outside. At the same time, summer and winter temperature extremes negatively impact the quality of fruits and seedlings [\[7](#page-11-0)[–9\]](#page-11-1). The corridor design of the solar greenhouse cluster can not only solve the above problems but also facilitate small mechanical cross-shed operations such as tillage, spraying, picking, transportation, etc. Additionally, the corridor can act as a plastic greenhouse for drying and other agricultural product processing [\[10–](#page-11-2)[13\]](#page-11-3). The solar greenhouse industry benefits from the corridor as well. To improve the production process's characteristics related to the service industry, crop displays can be arranged like a conventional urban health facility [\[14\]](#page-11-4). By showing a variety of plant species on both sides of the corridor, people will be better able to comprehend the kinds of plants grown in greenhouses and the conditions under which they thrive, giving the greenhouse an educational purpose [\[15\]](#page-11-5). Mechanized corridors, which connect greenhouses, crop displays, rest, and communication areas, are a crucial component of modern solar greenhouse clusters. They facilitate efficient and convenient operation and management of greenhouse clusters.

Due to the similarity in principle and form between corridors and plastic greenhouses, ventilation must be fully considered in the design. However, as an innovative greenhouse facility, the corridor still lacks extensive discussion among scholars. Numerous academics have studied greenhouse ventilation techniques, concentrating on ways to increase greenhouse ventilation effectiveness. He et al. [\[16\]](#page-11-6) employed computational fluid dynamics (CFDs) numerical simulations to investigate the impact of various vent sizes on the thermal environment of greenhouses, and a ventilation strategy for detachable north walls was proposed. This technique lowered the greenhouse's maximum temperature by approximately 5.8  $\degree$ C and its average temperature by about 1.7  $\degree$ C when compared to a con-venational brick wall solar greenhouse. The effects of environmental factors on the thermal environment of strawberry greenhouses with natural ventilation, including the air inlet size, outside temperature, and ambient wind speed, were examined and summarized by Fu and You [\[17\]](#page-11-7). Zhang et al. [\[18\]](#page-11-8) examined the connection between ventilation and humidity in Chinese solar greenhouses (CSGs) using a combination of the energy balance model and the CFDs model. It was discovered that while the temperature and humidity of CSGs decrease and exhibit a non-linear change process, the natural ventilation volume increases as ventilation openings increase. Through experiments and numerical simulations, Li et al. [\[19\]](#page-11-9) designed a ventilation scheme for a circular arched solar greenhouse and investigated the greenhouse's cooling and ventilation effects. Three ventilation structures were compared in terms of performance by Zhang et al. [\[20\]](#page-11-10): front bottom + top (FT), front bot-tom + back roof (FB), and front bottom + top + back roof (FTB). Upon comparing FTB to FT and FB, the cooling rate increased by 24.84% and 5.52%, respectively, while the average temperature dropped by 13.81% and 3.65%, respectively.

Corridor structures cannot, however, be directly affected by the findings of research on the ventilation in solar greenhouses. The way a corridor is built affects the entire greenhouse cluster and cannot be compared to the variations in humidity and temperature in a single solar greenhouse. As a result, studies on corridors should be conducted on a larger scale, comparable to that of building clusters in the construction sector, and cover the entire park [\[21\]](#page-11-11). Both the external wind field size of the 3D model [\[22\]](#page-11-12) and the choice of research variables to simplify the model [\[23\]](#page-11-13) are areas of extensive and well-developed experience. Moreover, corridors play an important role in the intensive production of greenhouses. Attempting to construct low-cost corridors and adopting natural ventilation can serve as a more sustainable and resource-saving method for promoting greenhouse vegetable cultivation [\[24\]](#page-11-14).

To sum up, corridors are an essential component of solar greenhouse cluster modernization. However, research on the use of corridors for facility agriculture production is scarce, as are studies on the most effective methods for maximizing corridor ventilation. Consequently, a mechanized corridor structure for solar greenhouse clusters is developed in this paper, and the temperature concentration phenomenon caused by the corridor In this paper, and the temperature concentration prichomenon caused by the corridor<br>structure is quantitatively explained. Then, in order to maximize the ventilation effect of the corridor, the effects of various factors are examined separately, including the corridor structure parameters, ventilation techniques, wind direction, and speed. This study can provide theoretical guidance for the corridor design of solar greenhouse clusters.

## **2.1. Geometric Model**<br>2.1. Geometric Model

As seen in Figure 1, the solar greenhouse cluster was made up of eight identical energysaving solar greenhouses. The dimensions of every solar greenhouse were 12 m in width, 60 m in length, and 6 m in height. The greenhouse's ventilation system was a combination<br>of hetters and ten south tion with two 60 m by 1 m yeartilation on wisco. The suscelescese of bottom and top ventilation, with two 60 m by 1 m ventilation openings. The greenhouses in the mechanized corridor. The separation between neighboring greenhouses were joined by the mechanized corridor. The separation between neighboring greenhouses was 15 m in the east and 9 m in the south. The corridor was 72.5 m long in the north–south direction, with a height of h (3.2, 3.7, 4.2, 4.7, 5.2 m) and a width of w (4, 5, 6, 7 m). The<br>two ways the carridow weapontilated were the top and hattery wortilation. The top window two ways the corridor was ventilated were the top and bottom ventilation. The top window had a width of 0.5 m and a length of 72.5 m. The bottom window had various bottom ventilation openings  $η$  (10%, 30%, 50%, 70%, and 90%) set, and it measured 1 m wide by 72.5 m long from the ground.

## *2.2. Mathematical Model 2.2. Mathematical Model*

The air flow in solar greenhouses and corridor follows the conservation equations of The air flow in solar greenhouses and corridor follows the conservation equations of mass, moment[um,](#page-11-17) and energy [27]. The finite element discretization method was primarily used in conjunction with them to analyze the fluid flow. Simplifying the analyzed model and reducing the calculation steps allowed for an effective analysis of air flow field.

$$
\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho \vec{v}) = S_{\mathbf{m}} \tag{1}
$$

$$
\frac{\partial}{\partial t}(\rho \vec{v}) + \text{div}(\rho \vec{v} \vec{v}) = \text{div}[\mu(\text{div}\vec{v})] - \text{div}P + \rho \vec{g} + \vec{F} + S \tag{2}
$$

$$
\frac{\partial}{\partial t}(\rho T) + \operatorname{div}(\rho \vec{v} T) = \operatorname{div}\left(\frac{\tau}{c}\operatorname{grad} T\right) + S_T \tag{3}
$$

where  $S_{\text{m}}$  represents the mass added to the continuous phase, kg;  $\stackrel{\rightarrow}{v}$  represents the speed,  $\frac{1}{2}$  m/s; *t* is time, s; and *ρ* represents the density, kg/m<sup>3</sup>.  $\overrightarrow{F}$  is the volume force, Pa; *µ* is *<sup>→</sup>* represents the  $\mathbf{p} \rightarrow \mathbf{p}$ ;  $\mathbf{p} \rightarrow \mathbf{p}$ ,  $\mathbf{$ the viscosity, Pa<sup>3</sup>, *P* is the pressure, Pa; *g*<sup>2</sup> is the gravitational decertation, *H*<sub>1</sub>, *S*<sup>2</sup>, *b*<sup>2</sup> is the momentum source term; T is the temperature,  $\degree C$ ; *τ* is the heat transfer coefficient, the viscosity, Pa·s; *P* is the pressure, Pa;  $\vec{g}$  is the gravitational acceleration, m/s<sup>2</sup>; *S* is<br>the momentum course term: *T* is the temperature,  ${}^{\circ}C$ : *T* is the heat transforme of ising the  $W/(m^2 \cdot ^{\circ}C)$ ; *c* is the specific heat capacity, J/(kg· $^{\circ}C$ ); and *S*<sub>T</sub> is the viscous dissipation term.

Due to the constant presence of turbulence in the corridor, different turbulence models have entirely different effects on the simulated temperature and flow fields. After comparing various turbulence models (RNG  $k$ - $\varepsilon$ , Standard  $k$ - $\varepsilon$ , and Realizable  $k$ - $\varepsilon$ ), this study's  $\frac{1}{2}$  imulation calculations used the Realizable *k-ε* model [\[28\]](#page-11-18). simulation calculations used the Realizable *k-ε* model [28].

$$
\frac{\partial(\rho k)}{\partial t} + \frac{\partial(\rho k u_i)}{\partial x_i} = \frac{\partial}{\partial x_j} \left[ \left( \mu + \frac{\mu_t}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right] + G_k - \rho \varepsilon \tag{4}
$$

$$
\frac{\partial(\rho\epsilon)}{\partial t} + \frac{\partial(\rho\epsilon u_i)}{\partial x_i} = \frac{\partial}{\partial x_j} \left[ \left( \mu + \frac{\mu_t}{\sigma_{\epsilon}} \right) \frac{\partial \epsilon}{\partial x_j} \right] + C_{1\epsilon} \frac{\epsilon}{k} G_k - C_{2\epsilon} \frac{\rho \epsilon^2}{k}
$$

#### gradients. *2.3. Assumptions and Boundary Conditions*

*2.3. Assumptions and Boundary Conditions* In this study, these assumptions were made to simplify the calculations: (1) air, both indoor and outdoor, was an ideal, incompressible gas; (2) air was thought of as a two-phase mixture consisting of dry air and water vapor; (3) the weather outside was favorable; and (4) the wind direction was constant over the whole simulation range.

Furthermore, the simulation model's accuracy was somewhat impacted by the choice of experimental materials. The enclosure structure's thickness, density, specific heat, and thermal conductivity were what determined how well the greenhouse and corridor are insulated. The greenhouse effect intensity was directly influenced by the rate at which each surface absorbs radiation. The material parameters of the model in numerical calculations are shown in Table [1.](#page-4-0) The solar radiation value is calculated using Fluent's built-in solar and the solar part of calculator, with the geographical location set to  $123.41°$  N,  $41.3°$  E, and a time zone of GMT + 8. The coefficient of sunny days is 0.9. **Materials Thickness,**

## 2.4. Correctness Verification model was validated by our research team in other studies *2.4.* Correctness **Verification**

The simulation model was validated by our research team in other studies [\[29,](#page-11-19)[30\]](#page-11-20). The model selection, boundary conditions, material parameters, and solver settings of this model have not changed. Here, it was not reiterated.<br>**3. Results** 

#### **3. Results and Discussion across the greenhouse and correlation across the greenhouse and correlation surfaces i**

The temperature distribution across the greenhouse and corridor surfaces is depicted in Figure [3.](#page-4-1) The solar greenhouse cluster's corridors have an unequal distribution of heat, which negatively affects the greenhouse's internal temperature distribution. To effectively control the temperature and humidity distribution in the corridor, this study simulated the structural parameters, ventilation techniques, wind speed, and direction of the corridor.

<span id="page-4-1"></span>

**Figure 3.** Temperature distribution of the corridor in the solar greenhouse cluster. **Figure 3.** Temperature distribution of the corridor in the solar greenhouse cluster.

## *3.1. Effect of Corridor Structure on Ventilation Effect*

## 3.1.1. Corridor Height

Figure [4a](#page-5-0) shows the internal temperature and humidity distribution of the corridor at different *h*. At this time, the width of the corridor is *w* = 5 m, and a combination of top and bottom ventilation is used. The corridor with  $h = 3.2$  m has a lower temperature. The temperature rises gradually as *h* increases because the heated area in the corridor also increases significantly. The heated area's size is the primary indicator of how *h* affects

temperature. There are comparatively fewer heating zones and colder temperatures in the corridors at lower heights. Additionally, the location within the corridor has an impact on the temperature distribution. The southern end of the corridor and the second horizontal intersection on the south side of the corridor are the two positions where the temperature is higher. In addition, the temperature distribution inside the corridor is completely different from that on the surface. The high temperature on the surface of the corridor is concentrated from that on the surface. The high temperature on the surface of the corridor is concentrated from that on the surface. The high temperature on the surface or the corridor is concentrated on the on the north side of the corridor, and the high temperature inside is concentrated on the south side of the corridor. The humidity distribution in the corridors with various  $h$  is depicted in Figure [4b](#page-5-0). At *h* = 3.2 m and *h* = 3.7 m, respectively, the humidity levels inside the corridor are the lowest and highest. Significant differences in humidity regulation are observed between corridors of varying heights. On the south windward side, there is a localized high humidity condition, and the quantity of air exchange in the corridor affects the water vapor content. Water vapor cannot be swiftly released due to the obstruction of the airflow on the south-windward side. concentrated on the corridor, and the high temperature inside is concentrated on the

and bottom ventilation is used. The corridor with *h* = 3.2 m has a lower temperature. The

<span id="page-5-0"></span>

Figure 4. Influence of h on the corridor ventilation: (a) Temperature distribution; (b) Humidity distribution; (c) Temperature fluctuation; (d) Temperature variations with time.

The average temperature values of corridors with various *h* are displayed in Figure The average temperature values of corridors with various *h* are displayed in Figure [4c](#page-5-0). At  $h = 3.7$  m, the corridor's temperature is noticeably higher than it is at other heights. Figure 4d shows that the corridor temperature increases more quickly after 15 s and then Figure [4d](#page-5-0) shows that the corridor temperature increases more quickly after 15 s and then stead in corridor temperature increases more questly and the statution steadily stabilizes after 30 s at  $h = 3.7$  m. In comparison to other corridor heights, the temperature rises most slowly and steadily at *h* = 5.2 m after 15 s. As a result, corridors with lower heights are more vulnerable to the greenhouse effect, which causes temperatures to rise more quickly between 15 and 25 s. When  $h = 5.2$  m, the corridor height is close to the greenhouse height, and the temperature rise is slower. This phenomenon is caused by the fact that the optical thickness of the corridor decreases with height, increasing the amount of short-wave radiation absorbed by the walls and ground, which has a higher absorption rate. Both experience a faster rise in temperature, which results in more longwave radiation being emitted and absorbed by greenhouse air. Convective heat transfer allows for a larger temperature differential between the air and its surface, which facilitates the easier extraction of energy. On the contrary, the rate of temperature rise is relatively small. But when  $h = 3.2$  m, the final corridor temperature is lower, which is the goal pursued by corridor ventilation. It is worth noting that the average body temperature (Figure [4d](#page-5-0)) is higher than the average temperature obtained by sampling (Figure [4c](#page-5-0)). This is caused by

the discrete radiation model's high temperature on the corridor's semi-transparent surface, so a thorough examination of both is needed.

higher than the average temperature obtained by sampling (Figure 4c). This is caused by

#### 3.1.2. Corridor Width At a height of *h* = 4.2 m, Figure 5a displays the temperature distribution of corridors

At a height of  $h = 4.2$  m, Figure [5a](#page-6-0) displays the temperature distribution of corridors with varying widths. A combination of top and bottom ventilation is used. The temperature is generally higher and varies greatly when  $w = 4$  m. For the 5 and 6 m wide corridors, there are variations in the quantity of anomalous data points as well as in the stability of temperature data. The overall uniformity and temperature distribution are better in the 7 m corridor. From Figure [5b](#page-6-0), during  $0 \sim 10$  s, the influence of corridor width on the temperature field is essentially the same. At different times, the influence of w on the temperature field  $\epsilon$ exhibits distinct patterns. Corridors with varying widths may affect the temperature field similarly in short times, but certain widths of corridors may see minor or large temperature increases in particular times. A corridor of  $w = 5$  m is the most appropriate, considering both the ventilation impact and construction cost.

<span id="page-6-0"></span>

Figure 5. Influence of  $w$  on the corridor temperature: (a) Temperature fluctuation; (b) Temperature variations with time.

## 3.2. Effect of Corridor Window Openings on the Ventilation Effect

### 3.2.1. Distribution of Ventilation Openings of the bottom and the correction of  $S$ temperature faster. However, combined ventilation may lead to temperature rise, while

Figure [6](#page-6-1) illustrates the impact of various window distributions on the corridor's temperature at  $h = 4.2$  m and  $w = 5$  m. It goes without saying that opening the top window alone has much less of a cooling effect than opening the bottom window alone and opening the top and bottom windows at the same time. Furthermore, the temperature drop rate is noticeably faster when the top and bottom windows are opened at the same time. rigure o mustrates the impact of various window distributions on the corridor s

<span id="page-6-1"></span>

**Figure 6.** Temperature variations at different positions with different ventilation openings. **Figure 6.** Temperature variations at different positions with different ventilation openings.

The corridor temperature and its variations over time under various ventilation methods are displayed in Figures [7a](#page-7-0) and [7b](#page-7-0), respectively, to further compare their cooling effects. The average temperature determined at various points during a 40 s corridor ventilation period is displayed in Figure [7a](#page-7-0). The corridor with only the top window open currently has the lowest and most consistent temperature. This may be because the hot air is effectively expelled from the corridor at this time. However, since this is an immediate effect, it does not follow that simply opening the top window for ventilation is preferable. The average temperature is highest but the temperature distribution within the corridor is more uniform when only the bottom window is open. Extremely low temperatures occur when the bottom and top windows are open at the same time, creating the most uneven temperature distribution in the corridor. This represents that the airflow inside the corridor is the most intense under this ventilation method.

<span id="page-7-0"></span>

**Figure 7.** Influence of window distribution on corridor temperature: (**a**) Temperature fluctuation; **Figure 7.** Influence of window distribution on corridor temperature: (**a**) Temperature fluctuation; (**b**) Temperature variations with time. (**b**) Temperature variations with time.

Tiguie 7D shows the tiend of the average body temperature of the corridor over<br>time under different ventilation methods. Compared to the other two methods, the top ventilation method has the slowest cooling rate. The ventilation effect of only opening the top window is poor and cannot effectively reduce the corridor temperature. Within the Figure [7b](#page-7-0) shows the trend of the average body temperature of the corridor over first 15 s, the cooling rate of combined ventilation is faster than that of bottom ventilation. When the bottom and top windows are opened simultaneously, it can lower the corridor temperature faster. However, combined ventilation may lead to temperature rise, while bottom ventilation may have a better cooling effect throughout the entire process. Therefore, when designing and managing corridors, it is necessary to comprehensively consider the characteristics of different window opening methods and choose appropriate ventilation strategies to achieve the best temperature regulation effect.

#### 3.2.2. Thermal Ventilation and Chimney Effect

A reduction in indoor pressure results from the easier expulsion of hot air from the top ventilation window when both the top and bottom windows are open. However, it cannot be ensured that outdoor air will always enter the room through the bottom window because of the large scale of the corridor. Figure  $8$  illustrates the analysis of the airflow direction at the window for this purpose. The air in the bottom window primarily flows into the corridor, while the air in the top window primarily flows out of the corridor, according to the proportionate distribution of air flow velocity. This indicates that thermal ventilation and chimney effect are important influencing factors that cannot be ignored in the ventilation form where the top and bottom windows are opened simultaneously.

<span id="page-8-0"></span>

**Figure 8.** Airflow distribution at the corridor window: (**a**) Bottom window; (**b**) Top window. **Figure 8.** Airflow distribution at the corridor window: (**a**) Bottom window; (**b**) Top window.

ventilation and chimney effect are important influencing factors that cannot be ignored in

3.2.3. Bottom Window Opening Ratio 3.2.3. Bottom Window Opening Ratio

As Figure [9a](#page-8-1) illustrates, the corridor temperature is also affected by the bottom window opening ratio *η*. The corridor's high-temperature zone and overall temperature are at their at their highest when *η* = 10%. In contrast, when *η* = 30%, 50% and 90%, the high-temperhighest when *η* = 10%. In contrast, when *η* = 30%, 50% and 90%, the high-temperature area usually on  $\eta$ of the corridor decreases, and the highest temperature area usually occurs on the south side of the corridor. Therefore, a modest opening of the bottom window can lessen the area that experiences high temperatures, thereby lowering the corridor's temperature and increasing comfort. In general, the corridor*'*s high-temperature region is the smallest and the temperature distribution is the most consistent when  $\eta$  = 70%. The impact of bottom window opening on corridor humidity is depicted in Figure [9b](#page-8-1). The highest humidity is at *η* = 10%. There is little difference in humidity when *η* is 30%, 50%, 70%, and 90%. Figure [9c](#page-8-1) shows that, following 40 s of ventilation, the temperature is lower as the bottom window mening *n* is 10% and 90%. The opening *η* is 10% and 90%. The temperature stabilizes and the data are most concentrated<br>whon *n* = 70% when  $\eta = 70\%$ .

<span id="page-8-1"></span>

**Figure 9.** Influence of  $\eta$  on the corridor ventilation: (a) Temperature distribution; (b) Humidity tribution; (**c**) Temperature fluctuation; (**d**) Temperature variations with time. distribution; (**c**) Temperature fluctuation; (**d**) Temperature variations with time.

As can be observed from Figure [9d](#page-8-1), the temperature is high, the cooling threshold is at its smallest, and the fluctuations are significant when *η* = 10%. After 10 s of cooling, the temperature stops dropping when  $\eta = 90\%$  and progressively gets closer to a steady state. This suggests that the temperature will not drop to its absolute minimum with excessive ventilation. When  $\eta = 30\%$ , 50%, and 70%, the indoor temperature rebounds within 10 s to 30 s. After 30 s, the temperature tends to stabilize, with a lower temperature at  $\eta = 70\%$ , indicating the best ventilation effect.

#### *3.3. Effect of Wind Speed and Direction on the Ventilation Effect* After determining the optimal parameters of the corridor structure (*h* = 3.2 m, *w* = 5 3.3.1. Wind Speed m) and the ventilation method (top ventilation  $\alpha$ ), the *n n*  $\alpha$  *n*  $\alpha$  *n*

After determining the optimal parameters of the corridor structure ( $h = 3.2$  m,  $w = 5$  m) and the ventilation method (top ventilation + bottom ventilation, with  $\eta = 70\%$ ), this section analyzes the influence of wind speed and direction on the corridor's ventilation effect.

Figure 10 illustrates the temperature variations in the corridor under various wind speed conditions  $(1.5 \text{ m/s}, 2 \text{ m/s}, 2.5 \text{ m/s}, 3 \text{ m/s}, \text{and } 3.5 \text{ m/s})$  when the solar greenhouse cluster is exposed to a south wind. Lower wind speeds often achieve better cooling effects, with lower turbulence intensity at ventilation openings and more stable airflow. Higher wind speeds increase the flow speed of air, causing heat in the air to be carried away faster. But currently, the turbulence intensity of the airflow is high, and the indoor air flow is chaotic, which also easily leads to obstruction of air discharge. Overall, at low wind speeds, it is still possible to effectively reduce temperature through air flow and achieve good cooling effects.

<span id="page-9-0"></span>

#### 3.3.2. Wind Direction

Figure [11a](#page-10-5) illustrates how the temperature inside the corridor exhibits a specific trend as the wind direction gradually varies from the east to the south. When the east and west winds are blowing downward, the temperature inside the corridor is lower and the data distribution is more concentrated. The optimal ventilation effect is achieved at this point because the airflow is perpendicular to the corridor opening and passes straight through it. When the south wind is blowing downward, the temperature is the highest. The airflow is parallel to the corridor's windows, making it difficult for air to enter the corridor. It is evident from Figure [11b](#page-10-5) that the trend of temperature variations varies with wind direction. The trends of the west and east directions almost overlap, suggesting that these two directions influence temperature regulation in a comparable way. After 10 s, the decline stops and experiences a brief rebound before continuing to decline again, gradually increasing after 40 s. The wind direction has a symmetrical effect on corridor ventilation. The greater the velocity component of the airflow perpendicular to the window, the more beneficial the ventilation is [\[31\]](#page-11-21).

<span id="page-10-5"></span>beneficial the ventilation is  $\mathcal{S}$
