Abstract: We present the case of a living-donor nephrectomy of a horseshoe kidney. The recipient was a 33-year-old male with a history of end-stage renal disease secondary to IgA nephropathy. The donor was his 33-year-old partner who on preoperative cross-sectional imaging was found to have a horseshoe kidney with a single artery, vein and ureter. The donor operation was performed using a laparoscopic hand-assisted technique with transection of the interpolar fibrotic band using a stapler device. The backtable organ preparation was performed in a standard fashion with addition of a reinforcing hemostatic suture of the stapled fibrotic band. The donated kidney was transplanted extraperitoneally in the right iliac fossa of the recipient. The patient had an unremarkable postoperative course and was discharged home on post operative day 2 with normalizing renal function. To our knowledge, this is the first living donor nephrectomy of a horseshoe kidney performed using a laparoscopic hand-assisted technique.

Keywords: horseshoe kidney; donor nephrectomy; kidney transplant

1. Introduction

A horseshoe kidney (HSK) is the most frequent renal fusion anomaly (1 in 400 to 800) [1–10] that involves abnormal migration of both kidneys with concomitant polar fusion. In over 90% of the cases this fusion occurs at the lower poles and as a result, two separate excretory renal units are maintained. The isthmus—which represents the fused portion—can be composed of renal parenchyma or a fibrous band and it may lie over or lateral to the midline. Because of this early fusion the kidneys fail to rotate medially during embryogenesis resulting in a ventral position of the renal pelvis with the ureters coursing in front of the lower poles. This may lead to abnormalities in the collecting system, therefore: urinary tract infections, vesicoureteral reflux, recurrent kidney stones and hydronephrosis, may frequently be observed [2,5–7]. Variation in the origin, number and size of the renal arteries and veins is well known and described as well, with only 30% of all HSK having a single renal artery on each side [5,7–9].

Due to all of this, concern for safety and feasibility of a living donor HSK has been questioned. However, according to the literature, since 1998, ten cases of successful HSK transplantation from live donors have been published (9 out of 10 from countries where deceased donation is not available) [1,11]. Outcomes are comparable with standard non-HSK donation with the most common complication reported being urinary leaks, likely due to the anterior situation of the urinary pelvis and the transected renal parenchyma [2,4,5,11].

Thorough pre-operative planning is paramount for a safe and successful operation. The protocol at our institution mandates a renal scintigraphy using technetium-99m-DTPA to estimate a relative glomerular filtration rate (GFR) for each kidney, in addition to a dynamic CT angiogram to assess renal morphology, vasculature and the excretory system.

2. Case Report

We present the case of a 33-year-old male with a history of end-stage renal disease secondary to IgA nephropathy who had been on hemodialysis for 3 months. Transplant evaluation deemed him an adequate candidate for transplantation, with his 33-year-old partner interested in living donation. She had no previous medical history and was found to have normal renal function. Technetium-99m-DTPA renal scintigraphy revealed estimated relative GFR values of 54.5% on the left and 45.5% on the right, in addition to a HSK (Figure 1). A dynamic CT angiogram showed contiguous renal parenchyma crossing the midline between the aorta and the inferior mesenteric artery, single right and left ureters, single right and left renal arteries, two right renal veins and a single left renal vein (Figure 2), in addition to volumetric reconstruction imaging (Figure 3). The left kidney was chosen for donation.

Figure 1. Technetium-99m-DTPA renal scintigraphy revealing an estimated relative GFR values of 54.5% on the left and 45.5% on the right, in addition to a HSK.

Figure 2. Dynamic CT angiogram with 3D reconstruction showing contiguous renal parenchyma crossing the midline between the aorta and the inferior mesenteric artery; single right and left renal arteries.

Figure 3. Volumetric CT reconstruction of the kidneys measuring 190.51 mL for the right kidney and 186.65 mL for the left kidney.

The donor operation was performed using a laparoscopic hand-assisted nephrectomy technique. After hilar dissection and isolation of the renal vasculature, the inter-polar fibrotic band was identified and transected at the midline using a vascular stapling device (Medtronic GIA™ Stapler Minneapolis, MN, USA). Hemostasis was confirmed without the need of further parenchymal hemostatic techniques and the donor nephrectomy was completed. On the backtable, the organ was prepared for transplantation in a standard fashion, with the addition of a reinforcing hemostatic running suture of the stapled fibrotic band using 6-0 permanent suture (Figure 4).

Figure 4. Picture of the explanted left kidney after backbench organ preparation. Note that the lower pole fibrotic band has been reinforced with a hemostatic running suture.

The donated kidney was transplanted extraperitoneally in the right iliac fossa, with the renal vein and renal artery anastomosed to the external iliac vein and artery respectively. A ureteroneocystostomy over a 6 Fr. double-J-stent was performed using the Lich-Gregoir technique. Induction immunosuppression therapy consisted of 20 mg of alemtuzumab administered upon incision. Tacrolimus, mycophenolate mofetil and methylprednisolone with a prednisone taper were used for maintenance immunosuppression. The patient had an unremarkable postoperative course and was discharged home on post operative day 2 with a creatinine level of 2.0 mg/dL, down from a preoperative level of 5.6 mg/dL. He was re-admitted to the hospital on post operative day 12 with mild acute kidney injury (AKI) and mild hydronephrosis secondary to ureteral stent obstruction. The stent was removed with rapid resolution of the AKI.

3. Discussion

Given the high likelihood of complex anatomical variation of HSK, both vascular and of the excretory system, the experience with these kidneys for living donation remains limited. The first split transplant of a HSK was performed by Politano in 1963 [3,8,10] and since then successful transplantation of both en-bloc and split horseshoe kidneys from deceased donors has been described with comparable outcomes to non-HSK [3,8,10,11]. In contrast to this experience, according to the literature, only 10 cases of successful living donation of HSK have been described [11]. Table 1. To our knowledge, this is the first case described using the laparoscopic hand-assisted technique.

Table 1. Living donor horseshoe kidney transplants described in the literature.

Author	Year	Surgical Approach	Complications
Aikawa	1998	Open (midline transperitoneal)	Urine leak
Inoue	2000	Open (left flank transperitoneal)	Urine leak
Goyal	2003	Open (left flank transperitoneal). (two transplants)	None Urine leak
Huser	2005	Open	None
Dinckan	2007	Open (left flank transperitoneal)	None
Sezer	2013	Open (retroperitoneal lumbotomy)	Ureteral obstruction
Kumar	2015	Open (left flank transperitoneal)	None reported
Justo-Janeiro	2015	Open (midline transperitoneal)	None
Sozener	2018	Open (left flank transperitoneal)	None
Galvez	2021	Laparoscopic hand-assisted	None

At our institution, all patients evaluated for potential renal living donation undergo a technetium-99m-DTPA renal scintigraphy to determine estimated GFR of each kidney, as well as dynamic CT angiogram to delineate vascular and excretory system anatomy. We consider this paramount to identify suitable donors, as well as for preoperative surgical planning.

The laparoscopic hand-assisted technique is safe and adds the benefits of a minimally invasive approach. The interpolar renal tissue can be safely divided with a laparoscopic stapling device and can later be reinforced with a running hemostatic suture in the backtable. Given the higher rate of urine leaks, particular attention should be paid to the transected interpolar tissue, both on the donor as well as the recipient, with addition of a running hemostatic suture of this tissue, as well as the use of an external drainage device.

4. Conclusions

Living donor nephrectomy of a HSK using a minimally invasive approach is a feasible operation with comparable outcomes to standard donation. Preoperative high-quality imaging that identifies location and morphology of the isthmus, as well as any vascular and excretory system variation, is paramount for successful outcomes.
